Abstract

To study the dynamics and mechanisms controlling activation of the heterotrimeric G protein $G\alpha 2\beta\gamma$ in *Dictyostelium* in response to stimulation by the chemoattractant cyclic AMP (cAMP), we monitored the G protein subunit interaction in live cells using bioluminescence resonance energy transfer (BRET). We found that cAMP induces the cAR1-mediated dissociation of the G protein subunits to a similar extent in both undifferentiated and differentiated cells, suggesting that only a small number of cAR1 (as expressed in undifferentiated cells) is necessary to induce the full activation of $G\alpha 2\beta\gamma$. In addition, we found that treating cells with caffeine increases the potency of cAMP-induced $G\alpha 2\beta\gamma$ activation; and that disrupting the microtubule network but not F-actin inhibits the cAMP-induced dissociation of $G\alpha 2\beta\gamma$. Thus, microtubules are necessary for efficient cAR1-mediated activation of the heterotrimeric G protein. Finally, kinetics analyses of $G\alpha 2\beta\gamma$ subunit dissociation induced by different cAMP concentrations indicate that there are two distinct rates at which the heterotrimeric G protein subunits dissociate when cells are stimulated with cAMP concentrations above 500 nM versus only one rate at lower cAMP concentrations. Quantitative modeling suggests that the kinetics profile of $G\alpha 2\beta\gamma$ subunit dissociation results from the presence of both uncoupled and G protein pre-coupled cAR1 that have differential affinities for cAMP and, consequently, induce G protein subunit dissociation through different rates. We suggest that these different signaling kinetic profiles may play an important role in initial chemoattractant gradient sensing.

Key words

Dictyostelium; chemoattractant; chemotaxis; cAMP; GPCR; heterotrimeric G protein; Bioluminescence Resonance Energy Transfer.

Abbreviations

BRET, bioluminescence resonance energy transfer; cAMP, cyclic adenosine monophosphate; cAR, cAMP receptor; 2'-dcAMP, 2'-deoxyadenosine-5'-monophosphate; EC50, half maximal effective concentration; FRET, Förster resonance energy transfer; GD, GDP-bound heterotrimeric G protein; GFP, green fluorescent protein; GPCR, G protein-coupled receptor; GT, GTP-bound heterotrimeric G protein; L, ligand; R, receptor; *Rluc*, *Renilla* luciferase; RMSE, root mean squared error.

1. Introduction

Chemotaxis, the ability of cells to sense gradients of chemicals (chemoattractants) and migrate towards their highest concentration, is a cellular behavior central to the embryonic development and immune response and that is deregulated in diseases such as cancer metastasis and inflammatory disorders. However, how cells detect and determine the direction of a chemoattractant gradient is not fully understood. Many chemoattractants are detected by seven transmembrane receptors that signal through heterotrimeric G proteins (G protein-coupled receptors; GPCRs), and studies with the chemotaxis experimental model *Dictyostelium discoideum* have provided important insight into chemoattractant GPCR signaling dynamics [1,2]. When food is abundant, *Dictyostelium* is in the growth (or vegetative) stage and grows as single undifferentiated cells [3]. Upon starvation, *Dictyostelium* enters a multicellular development/differentiation program going through aggregation (~4-8 h), mound (~12 h), slug (~16 h), and culmination (~18-24 h) stages that end with the formation of a fruiting body containing spores. Aggregation is mediated by the chemotaxis of cells towards cyclic AMP (cAMP). *Dictyostelium* has four cAMP receptors (cARs) [4,5]. cAR1 expression is maximal during aggregation and cAR3 levels rise towards the end of aggregation, whereas cAR2 and cAR4 are maximally expressed during the slug and culmination stages, respectively [6–9]. There is little cAR expressed in undifferentiated vegetative cells. cAR1 and cAR3 are most similar, with 56% amino acid identity, and they both mediate the response to cAMP through the heterotrimeric G protein $G\alpha 2\beta\gamma$. Although the two receptors display similar cAMP binding affinities in phosphate buffer, cAR3 is ~100 times less efficient than cAR1 in inducing cAMP-stimulated responses and cAR1 is essential for chemotaxis-driven aggregation through $G\alpha 2\beta\gamma$ [4,9,10]. Whereas there are twelve G alpha protein subunits in *Dictyostelium*, $G\alpha 2$ (gene *gpab*) is the main G alpha subunit responsible for the chemotactic responses to cAMP and there is only one G beta (gene *gpba*) and gamma subunit (gene *gpga*) [11–16].

The dynamics and mechanisms controlling cAR1- $G\alpha 2\beta\gamma$ coupling are not completely understood. The interaction between $G\alpha 2$ and $G\beta\gamma$ in live cells has previously been studied using a molecular proximity assay based on Förster (or fluorescence) resonance energy transfer (FRET) and has shown that the G protein subunit dissociation reflects their activation [17]. To investigate the dynamics of cAMP-induced $G\alpha 2\beta\gamma$ activation, we have used a similar molecular

proximity method, but based on bioluminescence resonance energy transfer (BRET), which we have recently adapted for use in *Dictyostelium* [18]. BRET is similar to FRET but functions with a bioluminescent enzyme (luciferase) as energy donor and, consequently, does not suffer from problems related to fluorescence excitation as in FRET [19]. Several BRET methods have been developed, which differ in the use of different luciferases, luciferase substrates, and fluorescent acceptor proteins [19,20]. We have used the BRET² method with the *Renilla* luciferase variant 2 (*Rluc2*) and GFP variant 2 (GFP²) [21,22]. We show that $G\alpha 2GFP^2$ and *Rluc2Gβ* are functional, that the BRET² signal detected in cells expressing both constructs reflects the interaction between the two G protein subunits, and that they behave as previously reported in experiments using FRET [17]. Our studies confirm that cAR1 is the main cAR mediating the cAMP-induced activation of $G\alpha 2\beta\gamma$, with negligible role of cAR3, and show that cAR1 induces $G\alpha 2\beta\gamma$ subunit dissociation to a similar extent in both undifferentiated and 5.5 h-differentiated cells. Interestingly, we observed that caffeine, which is commonly used to inhibit cAMP production and autocrine stimulation of *Dictyostelium* cells, increases the potency of cAMP to induce G protein subunit dissociation. Moreover, we found that disturbing the microtubule network but not F-actin inhibits the cAMP-induced $G\alpha 2\beta\gamma$ subunit dissociation, suggesting that microtubules facilitate coupling of cAR1 to the heterotrimeric G protein. Finally, kinetics analyses of the cAMP-induced $G\alpha 2\beta\gamma$ subunit dissociation responses indicate that elevated cAMP concentrations induces cAR1-dependent G protein dissociation through two distinct rates. Coupled to quantitative modeling, our observations lead us to propose that the two rates come from the presence of both uncoupled and $G\alpha 2\beta\gamma$ -pre-coupled cAR1 in resting cells, which have differential affinities for cAMP, and contribute to the initial response of cells exposed to elevated cAMP concentrations through distinct kinetics.

2. Materials and methods

2.1. Reagents

cAMP sodium salt monohydrate, 2'-deoxyadenosine-5'-monophosphate (2'-dcAMP) disodium salt, caffeine powder and anti-Flag M2 were from Sigma-Aldrich (St. Louis, MO, USA). 8-Bromo-cAMP from Enzo Life Sciences (Farmingdale, NY, USA). Coelenterazine 400a was purchased from Biotium (Fremont, CA, USA) and coelenterazine h was obtained from VWR (Radnor, PA, USA). Latrunculin A (Molecular Probes Invitrogen), Benomyl (Chem Service Inc) and Geneticin (GIBCO) were purchased from Thermo Fisher Scientific (Waltham, MA, USA). The Living Colors® GFP monoclonal antibody was purchased from Clontech (now Takara Bio USA Inc.; Mountain View, CA, USA) and the anti-Renilla luciferase antibody clone 5B11.2 was purchased from Millipore SIGMA (Darmstadt, Germany). HRP-conjugated secondary antibodies were purchased from Jackson ImmunoResearch Laboratories, Inc. (West Grove, PA, USA). The cAR1 antibody was a generous gift from Peter Devreotes (Johns Hopkins, Baltimore, MD) and is described elsewhere [23]. GFP-Tubulin and the extra-chromosomal vector pDM304 and pDM344 were obtained through the Dicty Stock Center, deposited by Doug Robinson (Johns Hopkins, Baltimore, MD) and Douwe Veltman, respectively [24–26]. Gα2-CFP/pDM358 and Gβ cDNA were gifts from Chris Janetopoulos (University of the Sciences, Philadelphia, PA) and described elsewhere [17]. The *Renilla* luciferase variant 2 (*Rluc2*; [21]) and GFP variant 2 (GFP²) were gifts from Michel Bouvier (Universite de Montréal, Montréal, Canada). The Lifeact-GFP construct was a gift from Rick Firtel (University of California–San Diego, La Jolla, CA) and was previously described [27–29].

2.2. Cell culture and strains used

Dictyostelium cells were grown attached to substrate in axenic HL5 medium including glucose (ForMedium, Hunstanton, Norfolk, UK) at 22°C and transformants were generated by electroporation. Transformed cells were selected in 20 µg/ml Geneticin and expression confirmed by immunoblot. Cells were differentiated by pulsing with 30 nM cAMP every 6 min for 5.5 h in 12 mM Na/K phosphate pH 6.1 at a confluency of 5X10⁶ cells/ml. The wild-type

cells used are AX3. *ga2* (*gpaB*), *gβ* (*gpbA*), and *carC*⁻ mutant cells were obtained from the Dicty Stock Center where they were deposited by Peter Devreotes (Johns Hopkins, Baltimore, MD) and described elsewhere [6,25,30]. The *carA*⁻ cells were generously provided by Alan Kimmel (NIH, Bethesda, MD) and the *carA*⁻*carC*⁻ cells (clone RI9) were a gift from Chris Janetopoulos and were both previously described [31,32].

2.3. DNA constructs and validation

All DNA constructs were generated with standard molecular cloning techniques. To make *Gα2GFP*²-pDM304, CFP in *Gα2CFP*-pDM358 was replaced by *GFP*² after residue 90 of the *Gα2* cDNA, using the *SpeI* restriction sites, and the hygromycin resistance cassette of pDM358 was replaced with the neomycin cassette from pDM304 by subcloning using restriction sites *BamHI* and *XhoI*. To make *Rluc2Gβ*, *Rluc2* was first cloned into the *BglII* restriction site of shuttle vector pDM344, eliminating the *BglII* site on the C-terminal end of *Rluc2* by ligating to a compatible *BamHI* site. *Gβ* was then cloned in C-terminal of *Rluc2* with the addition of a 4 amino acid linker (GSGS) using restriction sites *BglII* and *SpeI*. The *Rluc2Gβ*-containing *NgoMIV* cassette of pDM344 was subcloned into pDM304 and *Gα2GFP*²-pDM304 at the *NgoMIV* site, to generate *Rluc2Gβ*-pDM304 and *Rluc2Gβ*-*Gα2GFP*²-pDM304, respectively.

Primers sequences were as follows:

*GFP*² forward, AAGTGACTAGTATGGTGAGCAAGGGCGAGGAGCTG;

*GFP*² reverse, AAGTGACTAGTCTTGTACAGCTCGTCCATGC;

Rluc2 forward, AAGTGGGATCCAAAAAATGACAAGTAAAGTTTACGACCCCGA
GCAGAGG;

Rluc2 reverse, AAGTGAGATCTACCAGAACCACCCTGCTCGTTCTTCAGCACTC
TC;

Gβ forward, AAGTGAGATCTATGTCATCAGATATTTTCAGAAAAAATTCAACAA
GCAAGAAGAG;

Gβ reverse, AAGTGACTAGTTTAAGCCCAAATCTTGAGGAGAGAATCC.

The BRET constructs were verified by sequencing and validated as previously described [18]. Briefly, expression and integrity of the fusion constructs was verified by immunoblot using *Rluc* and *GFP* antibodies according to the manufacturer protocol; *Rluc2* and *GFP*² functionality

was verified by assessing luminescence with coelenterazine h at 480 nm and fluorescence at 510 nm, respectively, using a POLARstar Omega microplate reader (BMG Labtech, Ortenberg, Germany); and functionality of $G\alpha 2GFP^2$ and $Rluc2G\beta$ was verified by assessing rescue of the aggregation defects of $g\alpha 2^-$ and $g\beta^-$, respectively, by plating $G\alpha 2GFP^2/g\alpha 2^-$ and $Rluc2G\beta/g\beta^-$ cells on 12 mM Na/K phosphate agar plate and tracing the cells' development using a dissection microscope.

2.4. BRET² Assay and data analysis

The BRET² assay was performed as previously described [18]. Briefly, 1.5×10^6 cells was mixed with 5 μ M final Coelenterazine 400a in a 96-well white microplate. The BRET² signal was detected using a POLARstar Omega microplate reader (BMG Labtech, Ortenberg, Germany) by simultaneously measuring light through 370-450 nm and 500-530 nm filters. BRET² measurements were taken before and after injection of stimuli, where indicated, every 0.5 s at 22 °C. Injection of 12 mM Na/K phosphate buffer was used as control. For each measurement, the GFP² fluorescence signal detected at 500-530 nm was divided by the $Rluc2$ emission signal detected at 370-450 nm to calculate the BRET² ratio. The BRET² ratio obtained with cells expressing only $Rluc2G\beta$ (background control) was subtracted from that of cells expressing both $Rluc2G\beta$ and $G\alpha 2GFP^2$ to calculate the “net BRET²”. BRET² and net BRET² were then multiplied by 1000 to express the data as milli-BRET units (mBU). Where indicated, cells were pretreated with 5 μ M Latrunculin A for 15 min, or 50 μ M Benomyl for 15 min before they were used in the BRET² assay. The drugs were initially diluted in DMSO, which was at 0.5 % final concentration after dilution. 0.5 % DMSO in 12 mM Na/K phosphate buffer was then used as control. Cells were stimulated with the indicated final concentrations of cAMP in the presence of 10 mM DTT, diluted in 12 mM Na/K phosphate buffer. DTT is used to inhibit cell-secreted phosphodiesterases and prevent cAMP degradation [33], which could significantly change the cAMP concentration cells are exposed to, especially when using low doses. Dose-responses and kinetics analyses were performed using Prism (GraphPad Software Inc.) and MATLAB (MathWorks), respectively.

2.5. Imaging

Contrast images of developing cells were taken with a Motic digital dissecting microscope. DIC and fluorescence images were acquired using a Marianas Spinning Disk Confocal Workstation (Intelligent Imaging Innovations, In., Denver, CO, USA) equipped with an EvolveTM 512 EMCCD camera (Photometrics, Tucson, AZ, USA), and image analysis was performed using the Slidebook software (Intelligent Imaging Innovations, Denver, CO, USA). Where indicated, cells were treated with 5 μ M Latrunculin A for 15 min or 50 μ M Benomyl for 15 min before imaging.

2.6. Kinetics analyses

The net BRET² data was normalized using the average basal net BRET² measured before stimulation for each condition, which was set to 1. The net BRET² data were then fitted using the single exponential function: $BRET^2 = 1 + a(e^{-rt} - 1)$ or double exponential function: $BRET^2 = 1 + a_1(e^{-r_1t} - 1) + a_2(e^{-r_2t} - 1)$. Residuals of fitting are calculated by subtracting the data from the predicted values of the fit. To quantitatively determine the best fit, the error difference between single and double exponential fit was calculated as $\Delta E = \frac{RMSE_1 - RMSE_2}{RMSE_2}$, where $RMSE_1$ is the root mean squared error of the single exponential fit and $RMSE_2$ is that of the double exponential fit. From our analyses, we determined that a $\Delta E < 0.05$ indicates that the data can be fitted with a single exponential and a $\Delta E > 0.1$ indicates a double exponential function provides the best fit. A ΔE between 0.05 and 0.1 is ambiguous, meaning that the data could be fitted as well using a single or double exponential function. Every time curve obtained for different cAMP concentration was fitted using this standard, generating corresponding rates r (single rate) or r_1 and r_2 (two rates).

2.7. Computational modeling

Six reactions were considered to model the cAMP receptor coupling to and activation of heterotrimeric G protein $G\alpha 2\beta\gamma$. The first reaction is the basal level of receptor (R) pre-coupled to the inactive, GDP-bound heterotrimeric G-protein (GD) in the absence of cAMP ligand (L),

with rates k_1 and k_{-1} . The equation for pre-coupled receptor (RGD) without cAMP is defined as:

$$\frac{d[\text{RGD}]}{dt} = k_1[R][\text{GD}] - k_{-1}[\text{RGD}]$$

Without ligand, $[R] = R^{\text{tot}} - [\text{RGD}]$ and $[\text{GD}] = G^{\text{tot}} - [\text{RGD}]$. Consequently, the stable value of $[\text{RGD}]$ before adding L is obtained by setting $\frac{d[\text{RGD}]}{dt} = 0$, and this is also the initial value for $[\text{RGD}]$ after L is added:

$$[\text{RGD}]_{\text{initial}} = \frac{R^{\text{tot}} + G^{\text{tot}} + K_1 - \sqrt{(R^{\text{tot}} + G^{\text{tot}} + K_1)^2 - 4G^{\text{tot}}R^{\text{tot}}}}{2}$$

$K_1 = \frac{k_{-1}}{k_1}$ is the equilibrium dissociation constant and its reciprocal $\frac{1}{K_1}$ represents the binding affinity between R and GD. The second reaction is where L binds RGD to form LRGD, with rates k_2 and k_{-2} . The third reaction is where L binds R to form LR, with rates k_3 and k_{-3} . The fourth reaction is where LR then binds GD to form LRGD, with rates k_4 and k_{-4} . The fifth reaction is where the heterotrimeric G protein becomes active, GTP-bound (GT, with $G\alpha_2$ and $G\beta\gamma$ subunits dissociated) and dissociates from the receptor to form $\text{LR} + \text{GT}$. In *Dictyostelium* cells exposed to cAMP, because heterotrimeric G protein subunits don't adapt and display a steady state of activation as long as the stimulus is present (this study and [17]), we assume that this reaction is irreversible in the conditions used, with rate k_5 . The sixth reaction is considering the cycling of GT back to GD with re-association of the $G\alpha_2$ and $G\beta\gamma$ subunits upon GTP hydrolysis, which can then bind R or LR again, with rate k_6 . To quantitatively explain the observed dissociation kinetics and represent the whole activation/deactivation cycle of the heterotrimeric G protein, the following 4 ordinary differential equations were used:

$$\begin{aligned} \frac{d[\text{RGD}]}{dt} = & k_1(R^{\text{tot}} - [\text{RGD}] - [\text{LR}] - [\text{LRGD}])(G^{\text{tot}} - [\text{RGD}] - [\text{LRGD}] - [\text{GT}]) \\ & + k_{-2}[\text{LRGD}] - k_2[\text{RGD}][L] - k_{-1}[\text{RGD}] \end{aligned}$$

$$\begin{aligned} \frac{d[\text{LR}]}{dt} = & k_3[L](R^{\text{tot}} - [\text{RGD}] - [\text{LR}] - [\text{LRGD}]) + k_{-4}[\text{LRGD}] + k_5[\text{LRGD}] - k_{-3}[\text{LR}] \\ & - k_4[\text{LR}](G^{\text{tot}} - [\text{RGD}] - [\text{LRGD}] - [\text{GT}]) \end{aligned}$$

$$\begin{aligned} \frac{d[\text{LRGD}]}{dt} = & k_2[\text{RGD}][L] + k_4[\text{LR}](G^{\text{tot}} - [\text{RGD}] - [\text{LRGD}] - [\text{GT}]) - k_{-2}[\text{LRGD}] \\ & - k_{-4}[\text{LRGD}] - k_5[\text{LRGD}] \end{aligned}$$

$$\frac{d[GT]}{dt} = k_5[LRGD] - k_6[GT]$$

These equations were normalized for $R^{tot} = 1$, leaving 11 independent parameters. For every value of $[L]$, the equations were solved and the value $\frac{G^{tot}-[GT]}{G^{tot}}$ are compared to the normalized experimental data. The same procedure and standard as those for fitting the experimental data with single and double exponential functions were then used to obtain the exponential rates (r or r_1 and r_2) and amplitude of the response (a or $a_1 + a_2$) for the simulation results. These rates and amplitudes for different $[L]$ are then fitted to experimental data to identify proper values for the 11 parameters. This fitting was carried by employing a simulated annealing method, using the `simulannealbnd` function in MATLAB(R2015b) with default settings, as we previously reported [34,35]. First, an error function was defined as:

$$\text{Error} = \sum_i W_1(r_{1i}^s - r_{1i}^e)^2 + W_2(r_{2i}^s - r_{2i}^e)^2 + W_3(a_{1i}^s + a_{2i}^s - a_{1i}^e - a_{2i}^e)^2$$

r_1, r_2, a_1 , and a_2 are the exponential rates and response amplitudes obtained from a double exponential fit. When a single exponential fit is good, we set $r_1 = r_2 = r$ and $a_1 = a_2 = \frac{a}{2}$, where r and a are obtained from a single exponential fit. Subscript “i” represents the i th group with $[L] = [L]_i$. W is the weight of different terms that can be tuned. Superscript “s” means simulation results and “e”, experimental results. The simulated annealing prevents trapping the fit in a local minimum by accepting a trial step with some probability dependent on an artificial temperature T , even when this step does not improve the fit. The initial temperature was set to be high to allow for a larger searching area. Then, the temperature was gradually decreased, leading to more selective sampling towards the error decreasing direction. The position in the parameter space where the error function is minimal for each of the 11 parameters in the model was then determined: $k_1 = 0.002$; $K_1 = 0.962$; $k_2 = 0.007$; $K_2 = 1.24$; $k_3 = 0.502$; $K_3 = 78.4$; $k_4 = 0.214$; $K_4 = 1.04$; $k_5 = 0.905$; $k_6 = 0.075$; $G^{tot} = 0.989$. To simulate the heterotrimeric G protein subunit dissociation rates in the absence of pre-coupled receptors (RGD), the initial value for RGD was set to zero in the ODEs indicated above.

2.8. Statistics

Results are expressed as the mean of at least three independent experiments. Error bars represent SD for bar graphs and SE for dose-response curves. Statistical analysis was performed using the one-way ANOVA test.

3. Results and discussion

3.1. *Gα2* and *Gβ* subunits dissociation monitored by BRET²

To study heterotrimeric G protein activation in *Dictyostelium* by monitoring the interaction between the *Gα2* and *Gβγ* subunits using BRET², we used the *Renilla reniformis* luciferase variant 2 (*Rluc2*) and the BRET² energy acceptor GFP² [21,22]. We fused the luciferase in frame at the N-terminus of *Gβ* and inserted GFP² into the first loop of the helical domain of *Gα2*, based on previously reported and validated fluorescent protein constructs of *Gα2* [17]. To first determine if the *Gα2*GFP² and *Rluc2Gβ* constructs are functional, we expressed them individually in *Dictyostelium* cells lacking *Gα2* (*ga2*⁻ cells) and *Gβ* (*gβ*⁻ cells), respectively. *ga2*⁻ and *gβ*⁻ cells are unable to aggregate and undergo development but expression of exogenous *Gα2* or *Gβ* can rescue the developmental defects [14,16], which can then be used as a readout to determine if *Gα2* or *Gβ* constructs are functional. We observed that expression of *Gα2*GFP² and *Rluc2Gβ* in their respective null mutant strains rescues the ability of these cells to aggregate and develop into fruiting bodies, although not as numerous and large as those produced by wild-type cells (Fig. 1A). This is likely due to the fact that not all the cells express the constructs. Nonetheless, because expression of *Gα2*GFP² and *Rluc2Gβ* in their respective null mutant strain generates cells that are able to aggregate and develop indicates that the constructs are at least partly functional. Because we planned on using *ga2*⁻ cells for the BRET assays, we then expressed *Gα2*GFP² and *Rluc2Gβ* constructs together or *Rluc2Gβ* alone, which will serve as the background BRET control, in *ga2*⁻ cells. The co-expression of *Gα2*GFP² with *Rluc2Gβ* rescues the *ga2*⁻ cells developmental defects similarly to *Gα2*GFP² expression alone, indicating recovery of G protein signaling in these cells (Fig. 1A). Immunoblotting of cell lysates revealed proteins with apparent molecular weights of ~ 70 kDa for *Gα2*GFP² [calculated 71.9 kDa (*Gα2*, 43.6 kDa and GFP², 28.3 kDa)] and ~ 75 kDa for *Rluc2Gβ* [calculated 78.7 kDa (*Gβ*,

40.9 kDa, and *Rluc2*, 37.8 kDa)], respectively, indicating the successful expression of the expected fusion proteins in both *ga2⁻* and wild-type cells (Fig. 1B, S1A). In addition, cells expressing *Gα2GFP²* or *Rluc2Gβ* produce significant, above background fluorescence and luminescence signals, respectively, indicating properly folded and functional GFP² and luciferase moieties (Fig. 1C). Of note, we observed that the background luminescence and fluorescence signals in non-transformed WT and *ga2⁻* cells are considerably different in undifferentiated and 5.5 h-differentiated cells. The decrease in background fluorescence in 5.5 h-differentiated cells is actually consistent with a previous report showing that incubation of cells in phosphate buffer decreases autofluorescence that comes from vitamins in the growth medium [36]. However, we also observed an unexpected increase in the background luminescence signal in 5.5 h-differentiated cells compared to undifferentiated cells. This increase in luminescence indicates an increase in basal coelenterazine oxidation, in the absence of luciferase, and we believe that this is due to elevated superoxide production in developing *Dictyostelium* cells [37]. Nonetheless, altogether, our results indicate that the *Gα2GFP²* and *Rluc2Gβ* fusion constructs are functional.

To monitor the interaction between the two G protein subunits by BRET², we used 5.5 h-differentiated *Gα2GFP²/Rluc2Gβ*-expressing *ga2⁻* cells and *ga2⁻* cells expressing only *Rluc2Gβ*, to levels equivalent to those of cells expressing both constructs, to determine the background BRET² signal. When the two proteins were co-expressed, we detected a specific BRET² signal (62.6 ± 0.3 mBU) of ~ 3 fold over background detected in *Rluc2Gβ/ga2⁻* cells (22.8 ± 0.4 mBU), indicative of the interaction between *Gα2GFP²* and *Rluc2Gβ* (Fig. 2A). To assess the effect of cAMP stimulation on the G protein subunit interaction, we injected a saturating dose of cAMP (10 μM) while monitoring the BRET² signal in real-time before, during and after cAMP injection. We observed that cAMP stimulation leads to a rapid loss in the BRET² signal detected in *Gα2GFP²/Rluc2Gβ/ga2⁻* cells, up to ~30-40 decrease in total BRET² signal (63 to 36 mBU; Fig. 2A) reaching a steady state approximately 20 s after stimulation (Fig. 2B). cAMP stimulation of cells expressing *Rluc2Gβ* alone (Fig. 2A) or the injection of buffer to *Gα2GFP²/Rluc2Gβ*-expressing cells (Fig. 2B) has no effect, suggesting that the observed cAMP-induced decrease in BRET² signal in *Gα2GFP²/Rluc2Gβ/ga2⁻* cells reflects the cAMP-induced activation and dissociation of the heterotrimeric G protein subunits.

To further confirm that the *Gα2GFP²* and *Rluc2Gβ* can be used to study heterotrimeric G protein activation, we assessed their dissociation in response to different concentrations of cAMP.

We observed a dose-dependent decrease in BRET² signal between Gα2GFP² and Rluc2Gβ, with a measured EC₅₀ of ~29 nM (Fig. 2C). This EC₅₀ is similar to the K_d of the high affinity binding site of cAMP on cAR1 (~30 nM) for cells in a phosphate buffer similar to that we used in our experiments [4]. This is interesting because the cAR1 high affinity site was reported to represent only ~5-10% of the cAR1 population expressed during aggregation, with the remaining 90-95% having lower affinity (K_d of ~300 nM) [4,39]. It is possible, though, that the overexpression of the heterotrimeric G protein subunits affects this proportion and that there are more high affinity binding sites in the transformed cells. Nonetheless, the observation that the cAMP-induced G protein dissociation EC₅₀ is ~29 nM while stimulation with 250 nM cAMP almost inducing a full response, and 500 nM inducing the full response, suggests that the high affinity cAR1 sites (K_d ~30 nM) are the main mediators of cAMP-induced G protein subunits dissociation.

Of note, this cAMP-induced G protein dissociation EC₅₀ is slightly greater than what we previously reported in our recent BRET method article [18] as well as what was previously found for the G protein dissociation detected by FRET (~10 nM) [17]. The difference is that we and the other authors had previously pretreated the cells with caffeine to inhibit the production of cAMP and its autocrine stimulation of cells. To then directly assess if caffeine affects the cAMP-induced G protein dissociation, we treated our cells with 5 mM caffeine before measuring the change in BRET² upon cAMP stimulation. Interestingly, we observed that, in cells treated with caffeine analyzed in parallel to untreated cells, cAMP induces Gα2βγ subunits dissociation to a similar extent but with a significantly increased potency, with a measured half maximal effective concentration (EC₅₀) of ~4 nM (Fig. 2C). Therefore, our observation suggests that caffeine increases the potency of cAMP to induce Gα2βγ dissociation. We do not know the mechanism underlying the effect of caffeine on G protein dissociation, but a previous study of cAMP binding on whole cells showed that 10 mM caffeine leads to a conversion of most binding sites to the low affinity conformation [40]. Therefore, although we used a little less caffeine (5 mM) in our assay, it is unlikely that caffeine increases the potency of cAMP-induced Gα2βγ subunit dissociation by increasing the cAMP binding affinity. Caffeine inhibits cAMP production in *Dictyostelium* [41]. Consequently, the treatment of cells with caffeine became a popular method of preventing the autocrine stimulation of cells and, thereby, reducing the basal levels of biochemical activities in cells to facilitate their measurement in response to acute cAMP

stimulation. Whereas the mechanism of action of caffeine in *Dictyostelium* remains to be defined, our observation suggests that it affects more than just the autocrine stimulation of cells.

We also assessed G protein dissociation in response to the two well-characterized cAMP analogs, 2'-deoxy cAMP (2'-dcAMP) and 8-bromo cAMP (8-Br-cAMP) in the presence of caffeine as previously reported [17]. We measured EC50s of ~17 nM for 2'-dcAMP and ~3 μ M for 8-Br-cAMP, similar to the previously reported values (Fig. 2C). Therefore, these results, together with the cAMP-induced dissociation of G α 2 β γ subunits, are consistent with previous observations of G α 2 β γ subunit dissociation monitored by FRET [17]. In this study, Janetopoulos *et al.* also demonstrated that the cAMP-induced activation and dissociation of the G α 2 β γ subunits does not adapt to continuous stimulation. Instead, the G protein subunits reach a steady state of dissociation/activation as long as the stimulus is present, and after clearing of the cAMP the heterotrimeric G protein can be re-stimulated. Consistent with these previous findings, we observed that the loss of BRET² signal between G α 2GFP² and Rluc2G β upon stimulation of the cells with a saturating dose of cAMP persists as long as the stimulus is present (Fig. 2D). The BRET² signal is fully recovered when the stimulus is washed away, and the cells then respond to a re-stimulation with an equally effective loss of BRET² signal, indicating that the heterotrimeric G protein subunits re-associated upon removal of cAMP and re-dissociated upon application of the second stimulus. Altogether, our results indicate that the G α 2GFP² and Rluc2G β constructs are functional and, when expressed together, the resulting BRET² signal serves as readout of their interaction in live cells, which can then be used to study G α 2 β γ activation.

3.2. cAR1 mediates the cAMP-induced activation of G α 2 β γ in undifferentiated and differentiated cells.

Previous observations suggest that cAMP induces activation of some chemotactic pathways in undifferentiated cells as efficiently as in aggregation-competent cells [42]. To further investigate this, we compared the cAMP-induced activation of G α 2 β γ in undifferentiated and 5.5 h-differentiated, aggregation-competent cells. We detected similar basal net BRET² signals in both undifferentiated and 5.5 h-differentiated G α 2GFP²/Rluc2G β /g α 2⁻ cells, suggesting that a comparable proportion of G α and β γ subunits are interacting in resting conditions, independently of the cells' developmental stage (Fig. 3A). Interestingly, we observed

that cAMP stimulation of undifferentiated cells induces G protein subunits dissociation to similar extent and potency as that observed in 5.5 h-differentiated cells, with the same effect of caffeine on the EC50 (Fig. 3A and B). In addition, we observed similar cAMP-induced G protein subunits dissociations when expressing $G\alpha 2GFP^2$ and $Rluc2G\beta$ in wild-type cells, although the basal net BRET² signal in 5.5 h-differentiated wild-type cells was lower compared to undifferentiated wild-type cells (Fig. 3C).

The difference in basal net BRET² signal between undifferentiated and 5.5 h-differentiated wild-type cells could partly be due to the considerable reduction in $G\alpha 2GFP^2$ expression in differentiated wild-type cells compared to the undifferentiated cells, as detected by the decrease in fluorescence (Fig. 1C). This could also be due to the much increased cAR1 expression in differentiated wild-type cells, leading to increased basal $G\alpha 2\beta\gamma$ activity and dissociated subunits, which is not observed in the $ga2^-$ cells possibly because they have reduced cAR1 expression [14] (Fig. S2). In addition, the finding that cAMP stimulation of undifferentiated cells induces G protein subunit dissociation and, thus, activation, to the same extent as to that in 5.5 h-differentiated cells was unexpected. Although it is possible that overexpressing the G protein subunits disrupts the relative expression levels of other signaling components, cAR1 expression in undifferentiated cells is not increased as a result of $G\alpha 2GFP^2$ and $Rluc2G\beta$ expression (Fig. S2). As expected, we observed that cAR1 expression is equally very low in undifferentiated cells expressing or not $G\alpha 2GFP^2$ and $Rluc2G\beta$, whereas cAR1 is strongly increased in 5.5 h-differentiated wild-type cells. As previously reported, we observed that $ga2^-$ cells express much less cAR1 than wild-type cells, even after cAMP pulsing for 5.5 h, [43] and that expression of $G\alpha 2GFP^2$ and $Rluc2G\beta$ restores some of the cAR1 expression in differentiated $ga2^-$ cells, but to levels that remain considerably low. Therefore, our observations suggest that the low cAR1 expression levels in undifferentiated cells, and in $ga2^-$ cells expressing $G\alpha 2GFP^2$ and $Rluc2G\beta$, are sufficient to fully activate $G\alpha 2\beta\gamma$ in response to cAMP. Consequently, it is intriguing why cAR1 expression levels increase so much during aggregation (according to reported cAR1 mRNA levels: ~100 times more for cells growing on bacteria and developed on filters and ~1000 times more for axenic cells developed by cAMP pulsing) [6,44], which is believed to be essential for efficient chemotaxis to cAMP.

Since both cAR1 and cAR3 couple to $G\alpha 2\beta\gamma$, we assessed the contribution of both of these receptors to the measured cAMP-induced dissociation of $G\alpha 2\beta\gamma$ in undifferentiated versus

differentiated cells. We expressed $G\alpha 2GFP^2$ and $Rluc2G\beta$ in cells lacking cAR1 ($carA^-$ cells) and/or cAR3 ($carC^-$ and $carA^-carC^-$ cells), as well as in wild-type cells to use as control, and assessed the effect of cAMP stimulation on the BRET² signal. We observed that stimulation with a saturating cAMP concentration (10 μ M) of cells lacking cAR1 fails to induce considerable G protein subunit dissociation, whereas cells lacking only cAR3 display G protein subunit dissociation comparable to that in wild-type cells in both extent and potency (Fig. 3C and 3D). These results indicate that, in both undifferentiated and 5.5 h-differentiated cells, the detected cAMP-induced dissociation of $G\alpha 2\beta\gamma$ results from cAR1 stimulation, and that cAR3 must be expressed at levels too low to significantly contribute to this response in the conditions used.

3.3. Disrupting microtubules inhibits G protein subunit dissociation

A previous study showed that disrupting the actin cytoskeleton increases the mobility of cAR1 at the plasma membrane, whereas microtubule disruption inhibits cAR1's mobility and its mediated production of phosphatidylinositol 3,4,5-triphosphate [PI(3,4,5)P₃] in response to cAMP stimulation [45]. These observations suggested that the potential anchoring of cAR1 to microtubules is important for proper cAR1 signaling. To assess the effect of disrupting actin and microtubules on the cAR1-induced activation and dissociation of $G\alpha 2\beta\gamma$, we treated cells with the actin polymerization inhibitor Latrunculin A (LatA) [46] and the microtubule destabilizer Benomyl as previously reported [45]. Benomyl is a bioactive benzimidazole that, like nocodazole, specifically inhibits microtubule assembly by binding to tubulin subunits [47], but its effects on *Dictyostelium* were shown to be less severe than other microtubule destabilizers [48]. As expected, LatA and Benomyl treatment of cells leads to a loss of morphological cell polarity due to the disruption of F-actin and microtubule network, as observed using the F-actin reporter Lifeact-GFP and γ -tubulin-GFP, respectively (Fig. 4A and B). Disrupting actin or microtubules did not affect the interaction of $G\alpha 2$ with $\beta\gamma$ in resting cells, as observed by similar basal BRET² signals (Fig. 4C). Interestingly, whereas the LatA-mediated disruption of F-actin did not significantly affect the extent and potency of cAMP-induced G protein subunit dissociation, compared to vehicle (0.5% DMSO)-treated control cells, the Benomyl-mediated disruption of microtubules considerably inhibited G protein subunit dissociation (Fig. 4C and D). Note that treatment of cells with 0.5% DMSO produced a left-shift in the dose-response curve

compared to non-treated cells, similar to the effect of caffeine. We don't know how DMSO affects G protein dissociation. Nonetheless, although additional studies will be necessary to properly define the role of the cytoskeleton in G protein activation, our observations suggest that microtubules, and not actin, are important for the cAR1-induced activation of $G\alpha 2\beta\gamma$. These observations are consistent with previous work suggesting that F-actin does not play a significant role in the cAR1 coupling to and activation of $G\alpha 2\beta\gamma$ [45,49–51]. Moreover, the observation that intact microtubules are necessary for optimal cAR1-induced $G\alpha 2\beta\gamma$ activation provides a possible explanation for the reported dependency of cAMP-induced $PI(3,4,5)P_3$ production on an intact microtubule network [45].

3.4. Analysis of the cAR1-promoted $G\alpha 2\beta\gamma$ dissociation kinetics

To investigate the dynamics of cAMP-induced $G\alpha 2\beta\gamma$ activation, we measured G protein subunit dissociation in real-time in response to different cAMP concentrations and compared wild-type to *carC*⁻ cells to determine if cAR3 may contribute to the observed kinetics (Fig. 5, S3). Each time curve was fitted using single and double exponential decay and the goodness of fit was determined as described in the Materials and methods section (Table S1). Interestingly, we found that G protein subunits dissociation induced by cAMP concentrations of ~500 nM and below can be fitted with a single exponential whereas that induced by cAMP concentrations above 500 nM are best fitted with double exponentials with two rates (Fig. 5, S3, Table S1). Similar kinetics were observed using wild-type and *carC*⁻ cells, supporting our previous observation that the detected cAMP-induced $G\alpha 2\beta\gamma$ dissociation is mainly due to cAR1 and that the appearance of a second rate at higher cAMP concentrations is not due to cAR3 signaling (Fig. 5). Kinetics analyses of data obtained with $G\alpha 2GFP^2/Rluc2G\beta$ -expressing *ga2*⁻ cells also show similar results (Fig. S4).

Interestingly, the cAMP concentration at which the presence of a second G protein dissociation rate becomes obvious correlates with cAMP concentrations at which most of the low affinity cAR1 binding sites ($K_d \sim 300$ nM versus high affinity sites $K_d \sim 30$ nM) should be occupied [4]. Evidence suggest that the high affinity cAR1 binding sites in *Dictyostelium* are receptors already in complex with the G protein, as is the case for many mammalian GPCRs [16,52–58]. However, whether G protein pre-coupled cAR1 contributes to cAMP signaling is

debated [51,59]. To investigate the cAMP-induced $G\alpha2\beta\gamma$ dissociation kinetics profile, we considered a simple model of receptor-G protein coupling, in which both free cAR1 (R) and cAR1 pre-coupled to inactive $G\alpha2\beta\gamma$ (RGD) potentially exist in an equilibrium in resting cells (Fig. 6A). In our model, we postulate that upon stimulation with cAMP ligand (L), the latter can bind to R or RGD to generate LR and LRGD, respectively. In turn, LR then recruits GD to also lead to LRGD. Formation of LRGD stimulates exchange of GDP for GTP on the G protein, thereby activating it leading to LR + GT. In *Dictyostelium*, evidence suggest that the $G\alpha2\beta\gamma$ subunits dissociate upon activation, so we consider that $GT = G\alpha2 + G\beta\gamma$ [17,49–51]. Upon GTP hydrolysis on $G\alpha2$, the subunits then re-associate to form GD that can be activated again as long as cAMP is present. Six reactions total are considered, as shown in Fig. 6A and described under Materials and methods. In our scheme, the appearance of two rates of G protein dissociation for higher cAMP concentrations is due to increased cAMP binding to uncoupled receptors to which it has lower affinity. Our scheme also incorporated that cAMP binding to lower affinity, uncoupled receptors produces a slower G protein activation response due to the additional G protein recruitment step. We generated a quantitative model of this scenario including both uncoupled (R) and pre-coupled receptors (RGD) that can simulate the kinetics data very well (Model R + RGD; Fig. 6B). Using this model, when we simulate the responses in the absence of pre-coupled receptors (Model R), we obtain only one rate throughout the range of cAMP concentrations used, supporting the hypothesis that one of the rates comes from binding to pre-coupled receptors (Model R; Fig. 6B).

In a previous study, Xu *et al.* considered the role of three possible cAR1 coupling mechanisms during chemotaxis: (1) $R+GD \rightarrow RGD+L \rightarrow LRGD \rightarrow LR+GT$ (with receptor pre-coupling); (2) $L+R \rightarrow LR+GD \rightarrow LRGD \rightarrow LR+GT$ (no pre-coupling); and (3) the previous two mechanisms combined (co-existence of uncoupled and pre-coupled receptors) [51]. As their results show that persistent ligand stimulation results in steady-state G protein activation, coupling mechanism (1) was ruled out, as it cannot allow a persistent cycle. However, the model of Xu *et al.* did not allow quantitatively discriminating between mechanisms (2) and (3) and, thus, did not determine whether pre-coupled receptors contribute to G protein activation during chemotaxis to cAMP. Compared to the model by Xu *et al.*, our model uses fewer intermediate steps, parameters and variables, and does not have any spatial dynamics, which makes it easier to quantitatively fit our experimental data and provide insight into potential coupling mechanisms

underlying the two G protein subunits dissociation rates that we observe. Our results suggest that pre-coupled receptors play a role in the rapid activation of the heterotrimeric G protein upon cAMP stimulation. Consequently, our results suggest that mechanism (3) described above, which includes contribution of both uncoupled and pre-coupled receptors, is likely the mechanism for cAMP-induced activation of heterotrimeric G proteins.

To test the prediction that the two cAMP-induced G protein dissociation rates are related to the high and low affinity cAR1 binding sites, we performed an experiment in which we stimulated the cells with two sequential cAMP concentrations. For the first stimuli, we used sub-saturating cAMP concentrations of 10, 20, and 50 nM, and we used a saturating cAMP concentration of 10 μ M for the second stimuli (Fig. 6C). We postulated that lower doses of cAMP would preferentially bind and activate high affinity cAR1 sites, reducing the number of high affinity sites available for the second stimulus. Consequently, the double exponential in the G protein dissociation profile from stimulation with 10 μ M cAMP would become gradually less obvious as the strength of the first stimulus increases. As an additional control, we also stimulated cells with 10 nM cAMP followed by a second stimulus with sub-saturating cAMP concentration of 300 nM. We analyzed the kinetics of the response after the second stimulus and compared to that obtained with cells directly stimulated with 10 μ M cAMP. To determine the best fit for the data, we calculated the error difference (ΔE) between single and double exponential fit. We found that the 10 μ M cAMP-induced response has decreasing ΔE as the concentration of the first cAMP stimulus increases (Fig. 6D). On the other hand, the 300 nM cAMP-induced response, following the first 10 nM cAMP stimulation, is fitted equally well with single and double exponentials (Fig. S5). Therefore, these results support the hypothesis that, in resting cells, two cAR1 sites of differential affinities for cAMP underlie the two rates observed when cells are stimulated with elevated, saturating cAMP concentrations.

cAR1 expressing cells have high and low affinity binding sites for cAMP with K_d of $\sim$ 30 and 300 nM, respectively [4]. Previous observations suggest that the high affinity cAMP binding sites are G protein-dependent [16,57,58]. The cAMP concentrations inducing G protein subunit dissociation through two distinct rates correlate with cAMP concentrations at which both high and low affinity binding sites would be occupied. Therefore, we propose that the kinetics of cAMP/cAR1-induced G protein subunit dissociation that we observe result from the co-existence, in resting cells, of both uncoupled and pre-coupled cAR1 that have differential affinities for

cAMP. At cAMP concentrations of ~500 nM and below, mostly high affinity pre-coupled cAR1 sites are occupied and promote $G\alpha 2\beta\gamma$ activation, reflected by only one rate of G protein subunit dissociation. However, at cAMP concentrations above 500 nM, both high affinity pre-coupled cAR1 and low affinity uncoupled cAR1 sites are occupied. In this case, pre-coupled cAR1 leads to rapid G protein activation while uncoupled cAR1 first needs to recruit $G\alpha 2\beta\gamma$ before activating it, which we propose results in two distinct rates of G protein subunit dissociation.

Although cAMP binding affinities and cAR1 pre-coupling can explain the G protein dissociation rates, other factors may also contribute to the observed kinetics. Previous studies showed the presence of an intracellular pool of G proteins that undergo regulated translocation to the plasma membrane of *Dictyostelium* cells upon stimulation with higher cAMP concentrations [49,60]. The cAR1 recruitment and activation of this translocated pool of G proteins at high cAMP concentrations likely plays a role in the observed second rate of G protein dissociation. Furthermore, although cAR1 has been extensively studied, both the pharmacology and G protein coupling of cAR1 may be more complicated than what we currently know. For instance, many mammalian GPCRs are known to form homo- or hetero-oligomers, which can affect GPCR function in different ways, including modulating ligand binding and G protein coupling [61–63]. Whether cAR1 forms dimers or higher oligomers remains to be determined but it is possible that cAMP stimulation actually alters cAR1's oligomeric state, which could then lead to inducing G protein dissociation through distinct rates. Nonetheless, our findings indicate that initial cAMP stimulation of resting *Dictyostelium* cells occurs through two distinct rates that correlate with the high and low affinity cAR1 sites. Consequently, we propose that these different signaling dynamics may play a role in initial gradient sensing. On the other hand, during chemotaxis, when cells are constantly exposed to a cAMP gradient and the heterotrimeric G protein is predicted to continuously and rapidly cycle between active and inactive states, it is possible that only uncoupled cAMP-bound cAR1 (LR) exists in this situation, cycling between LR and LRGD forms as previously proposed by Xu *et al.* [51].

4. Conclusion

We used BRET² to investigate the dynamics and regulation of heterotrimeric G protein $G\alpha 2\beta\gamma$ activation in response to cAMP stimulation in *Dictyostelium* by monitoring the

dissociation of $G\alpha_2$ and $G\beta$. Our findings indicate that cAR1 is the main receptor promoting $G\alpha_2\beta\gamma$ activation in both undifferentiated and 5.5 h-differentiated cells, that only very low levels of cAR1 expression are necessary to induce full activation of $G\alpha_2\beta\gamma$, and suggest that caffeine increases the potency of cAMP-induced G protein subunit dissociation, although the mechanism remains unknown. In addition, our findings suggest that F-actin does not affect the coupling of cAR1 to $G\alpha_2\beta\gamma$ but that an intact microtubule network is necessary for efficient cAMP-induced G protein subunit activation. Finally, our kinetics analyses and receptor-G protein coupling modeling studies reveal two rates of cAMP-induced G protein subunits dislocation that highly correlate with cAR1 binding sites, leading us to propose that both uncoupled, low affinity, and $G\alpha_2\beta\gamma$ -coupled, high affinity, cAR1 exist in resting cells leading to the observed two rates of G protein subunit dissociation when cells are exposed to elevated cAMP concentrations. Although the study of protein-protein interactions by BRET is currently limited to measuring responses to acute stimulations, the information gained from these studies provide insights into how cells initially respond to chemoattractant exposure and into mechanisms possibly involved in sensing gradients.

Acknowledgments

Figure legends

Fig. 1. Validation of *Rluc2Gβ* and *Gα2GFP²* fusion constructs.

A, Pictures show the morphological phenotype of developing cells at 24 h after initial plating on non-nutrient agar. B, Expression of *Rluc2Gβ* and *Gα2GFP²* in cells lacking *Gα2* (*gα2⁻*). Immunoblots (IB) using anti-GFP and anti-Renilla Luciferase (Luc) antibodies are shown. Wild-type (WT) cells and *gα2⁻* cells were used as control. C, Measurements of luminescence at 370-450 nm, produced upon addition of coelenterazine h, and fluorescence at 500-530 nm, produced upon excitation of the samples at 450-470 nm. Luminescence and fluorescence are reported in relative light units (RLU) for WT and *gα2⁻* cells (background levels), and cells expressing *Rluc2Gβ* alone or together with *Gα2GFP²*. The errors represent standard deviation. Results are expressed as the mean or are representative of at least three independent experiments.

Fig. 2. *Gα2βγ* subunits dissociation detected by BRET² reflects activation.

A, BRET² measurements obtained from *gα2⁻* cells expressing *Rluc2Gβ* alone or together with *Gα2GFP²* before and after 1 min stimulation with 10 μM cAMP. Error bars represent the standard deviation. B, Representative net BRET² values obtained from measurements taken continuously every 0.5 s before, during and after injection of either buffer as control or 10 μM cAMP to *Gα2GFP²/Rluc2Gβ/gα2⁻* cells. Solid arrow indicates stimulus injection. C, Net BRET² values for *Gα2GFP²/Rluc2Gβ/gα2⁻* cells stimulated with different concentrations of the indicated cAR1 ligands, expressed as % of the net BRET² levels in non-stimulated cells. cAMP dose-responses were measured in the presence (+caff) and absence of 5 mM caffeine. LogEC50 (effective concentration of ligand producing 50% of the maximal stimulation) values are indicated with their standard errors, and EC50 values are indicated in parentheses, for each ligand and condition. Error bars represent the standard error. * $p < 0.0001$. D, Net BRET² values before and after a first stimulation of *Gα2GFP²/Rluc2Gβ/gα2⁻* cells with 5 μM cAMP are indicated under 1° stimulus. One min after the first stimulus, cells were washed twice with 12 mM Na/K phosphate buffer and the net BRET² of the same cells was measured again before and after stimulation with 10 nM or 10 μM cAMP (2° stimulus). Error bars represent the standard deviation. mBU, milli BRET² units. Results are expressed as the mean of at least three independent experiments.

Fig. 3. cAR1-induced Gα2βγ subunits dissociation in undifferentiated and 5.5 h-differentiated cells.

A, Net BRET² values for measurements obtained before and after 10 μM cAMP stimulation of undifferentiated and 5.5 h-differentiated Gα2GFP²/Rluc2Gβ/gα2⁻ cells. B, Net BRET² values for measurements obtained of Gα2GFP²/Rluc2Gβ/gα2⁻ cells stimulated with different cAMP concentrations, expressed as % of the net BRET² levels in non-stimulated cells. LogEC50 values are indicated with their standard errors, EC50 values are indicated in parentheses. * p < 0.001. C, Net BRET² values for measurements obtained of undifferentiated and 5.5 h-differentiated wild-type (WT) cells and cells lacking cAR1 (*carA*⁻), cAR3 (*carC*⁻) or both cAR1 and cAR3 (*carA*⁻*carC*⁻), expressing Gα2GFP² and Rluc2Gβ before and after stimulation with 10 μM cAMP. D, Net BRET² values for measurements obtained of WT and *carC*⁻ cells expressing Gα2GFP² and Rluc2Gβ stimulated with different cAMP concentrations, expressed as % of the net BRET² levels in non-stimulated cells. LogEC50 values are indicated with their standard errors, EC50 values are indicated in parentheses. * p < 0.05. Results are expressed as the mean of at least three independent experiments. Error bars represent the standard deviation in bar graphs and standard error in dose-response curves.

Fig. 4. The role of F-actin and microtubules in cAMP-induced Gα2βγ subunits dissociation.

A, Differential interference contrast (DIC) and Lifeact-GFP fluorescence confocal images of 5.5 h-differentiated wild-type cells treated either with 0.5 % DMSO (vehicle control) or 5 μM Latrunculin A (LatA) for 15 min. B, DIC and Tubulin-GFP fluorescence confocal images of 5.5 h-differentiated wild-type cells treated either with 0.5 % DMSO (vehicle control) or 50 μM Benomyl for 15 min. C, Net BRET² values for measurements obtained before and after 10 μM cAMP stimulation of 5.5 h-differentiated Gα2GFP²/Rluc2Gβ/gα2⁻ cells pretreated with 0.5 % DMSO as control, 5 μM LatA or 50 μM Benomyl for 15 min. D, Net BRET² values for measurements obtained with Gα2GFP²/Rluc2Gβ/gα2⁻ cells pretreated with 0.5 % DMSO as control, 5 μM LatA or 50 μM Benomyl for 15 min, and stimulated with different cAMP concentrations. Data are expressed as % of the net BRET² levels in non-stimulated cells. LogEC50 values are indicated with their standard errors, EC50 values are indicated in

parentheses. * $p < 0.001$. Results are expressed as the mean or are representative of at least three independent experiments. Error bars represent the standard deviation for the bar graph and standard error for the dose-response curves.

Fig. 5. Kinetics analyses of cAMP-induced $G\alpha 2\beta\gamma$ subunits dissociation.

A, Net BRET² values for measurements taken every 0.5 s after stimulation of wild-type (WT) cells and *carC*⁻ cells expressing $G\alpha 2GFP^2$ and *Rluc2Gβ* with 10 nM or 10 μM cAMP, normalized to net BRET² levels before stimulation. The curves were fitted using single and double exponential functions. For the 10 nM data, the fits are identical and overlap. B, Residuals for single and double exponential fittings for the 10 μM cAMP-stimulated conditions shown in A were calculated by subtracting the measured values from the fitted values. C, Rates of $G\alpha 2\beta\gamma$ subunits dissociation determined from the time curve fittings obtained for 10 nM, 100 nM, 500 nM, 1 μM, 10 μM, and 50 μM cAMP stimulations of WT and *carC*⁻ cells. Results represent the mean or the analyses of at least three independent experiments.

Fig. 6. Quantitative modeling of the observed $G\alpha 2\beta\gamma$ subunits dissociation kinetics.

A, Conceptual model of cAR1- $G\alpha 2\beta\gamma$ coupling. The constants are defined in the Materials and Methods section. B, Rates of $G\alpha 2\beta\gamma$ subunits dissociation induced by different concentrations of cAMP obtained from analyzing the experimental data for wild-type cells from Fig. 5C (red circles) and from quantitatively modeling the responses where both uncoupled (R) and pre-coupled (RGD) cAR1 bind the cAMP ligand (L) or where only uncoupled cAR1 is present and mediates the response to cAMP (black curves). C, Representative net BRET² values obtained from measurements taken continuously every 0.5 s before, during and after injection of a first cAMP stimulus of 10, 20, or 50 nM at 10 s, and of a second cAMP stimulus of 10 μM at 60 s of $G\alpha 2GFP^2/Rluc2G\beta/g\alpha 2^-$ cells. Solid arrows indicate when the cAMP stimuli were injected. D, Calculated error differences (ΔE) for single and double exponential fittings of the $G\alpha 2\beta\gamma$ subunits dissociation kinetics induced by 10 μM cAMP stimulation alone (from data presented in Fig. 5A) or after the first stimuli indicated in C. ΔE calculations and interpretations are described in the Materials and Methods section and main text. Results represent the mean or the analyses of at least three independent experiments.

Fig. S1. Expression of *Rluc2Gβ* and *Gα2GFP²* in wild-type (WT) cells.

A, Immunoblots (IB) using anti-GFP and anti-Renilla Luciferase (Luc) antibodies are shown. Non-transformed WT cells were used as control. B, BRET² measurements obtained from WT cells expressing *Rluc2Gβ* alone or together with *Gα2GFP²* before and after 1 min stimulation with 10 μ M cAMP. Data are representative or represent the analyses of at least three independent experiments. Error bars represent the standard deviation. mBU, milli BRET units.

Fig. S2. Expression of cAR1 in undifferentiated (0 h developed) and 5.5 h-differentiated WT and *ga2* null cells with and without expression of Gα2GFP² and Rluc2Gβ. Immunoblot (IB) using anti-cAR1 antibody is shown and is representative of three independent experiments. M, Molecular marker.

Fig. S3. net BRET² data and additional kinetics analyses of cAMP-induced Gα2βγ subunit dissociation in WT and *carC* null cells used to generate the data presented in main Fig. 5C. A, net BRET² data for measurements taken every 0.5 s before and after stimulation with the indicated cAMP concentrations. B, net BRET² data normalized to levels before stimulation and the curves were fitted using single (black) and double (red) exponential functions. The residuals analysis for each curve fitting is included to the right of corresponding time curves. Results represent the analyses of at least three independent experiments. mBU, milli BRET units.

Fig. S4. Kinetics analyses of cAMP-induced Gα2βγ subunit dissociation in Gα2GFP2/Rluc2Gβ-expressing *ga2* null cells. A, net BRET² measurements taken every 0.5 s after stimulation with 10 nM or 10 μM cAMP, normalized to BRET² levels before stimulation. The curves were fitted using both single and double exponential functions. For the 10 nM data, the fits are identical and on top of each other. B, Residuals for single and double exponential fittings for the 10 μM cAMP-stimulated conditions shown in A were calculated by subtracting the fitted values from the measured values. C, Gα2βγ subunit dissociation rates determined from the time curve fittings of data obtained for 2.5 nM, 5 nM, 10 nM, 12.5 nM, 25 nM, 50 nM, 100 nM, 200 nM, 500 nM, 1 μM, 10 μM, and 50 μM cAMP stimulations. Results represent the analyses of at least three independent experiments.

Fig. S5. Sequential stimulation of Ga2GFP²/Rluc2Gβ-expressing wild-type (WT) cells with 10 nM and 300 nM cAMP. A, net BRET² values obtained from measurements taken continuously every 0.5 s before, during and after injection of a first cAMP stimulus of 10 nM at 10 s, followed by a second cAMP stimulus of 300 nM at 60 s. Solid arrows indicate when the stimuli were injected. B, net BRET² measurements taken every 0.5 s after stimulation with the second stimulus of 300 nM, normalized to BRET² levels right before this stimulation. The data were fitted using single and double exponential functions. C, Residuals for single and double exponential fittings for the 300 nM cAMP-stimulated conditions shown in B were calculated by subtracting the measured values from the fitted values. mBU, milli BRET units.

cAMP (nM)	ΔE (WT)	ΔE (<i>carC</i> ⁻)
10	-0.010	-0.010
100	-0.010	0.037
1000	0.173	0.275
10000	0.391	0.483
50000	0.225	0.346

Table S1. Calculated thresholds used to determine the function that best fit the G protein dissociation kinetics obtained for different cAMP concentrations.

Error differences (ΔE) were calculated as indicated in the Materials and Methods section for wild-type cells (WT) and cells lacking cAR3 (*carC*⁻). $\Delta E < 0.05$ indicates a single exponential function fits the data, $\Delta E > 0.1$ indicates a double exponential function best fits the data. The dashed line indicates where the fits switch between single and double exponential.
