Statement of Translational Relevance

With further evidence from larger cohorts, the risk of ovarian cancer algorithm (ROCA) based on longitudinal serum CA125 measurements could be applied to women at increased genetic/familial risk who elect screening for early detection of ovarian cancer. ROCA personalizes screening to a woman's unique CA125 level, using each woman as her own control, resulting in a more precise screening test. Shifting transvaginal ultrasound from concurrent with CA125 (the present standard) to secondary triage only in women with abnormal ROCA results greatly reduces ultrasound-related false-positive tests. However, consideration of risk-reducing salpingo-oophorectomy (RRSO) upon completion of child bearing and when ovarian cancer risk increases above population risk is and should remain the current standard of care for *BRCA1/2* mutation carriers. If further studies determine ROCA is effective, this improved approach to early detection would be available to increased risk women who choose, despite a strong recommendation for RRSO, to postpone their surgery.

Abstract

Purpose: Women at familial/genetic ovarian cancer risk often undergo screening despite unproven efficacy. Research suggests each woman has her own CA125 baseline; significant increases above this level may identify cancers earlier than standard 6-12 monthly CA125>35U/mL.

Experimental Design: Data from prospective Cancer Genetics Network and Gynecologic Oncology Group trials, which screened 3,692 women (13,080 woman-screening years) with a strong breast/ovarian cancer family history or *BRCA1/2* mutations, were combined to assess a novel screening strategy. Specifically, serum CA125 q3 months, evaluated using a risk of ovarian cancer algorithm (ROCA), detected significant increases above each subject's baseline, which triggered transvaginal ultrasound. Specificity and PPV were compared with levels derived from general population screening (specificity 90%, PPV 10%), and stage-at-detection was compared with historical high-risk controls.

Results: Specificity for ultrasound referral was 92% *vs.* 90% (p=0.0001), and PPV was 4.6% *vs.* 10% (p>0.10). Eighteen of 19 malignant ovarian neoplasms (prevalent=4, incident=6, RRSO=9) were detected *via* screening or risk-reducing salpingo-oophorectomy (RRSO). Amongst incident cases (which best reflect long-term screening performance), 3/6 invasive cancers were early-stage (I/II) (50% *versus* 10% historical *BRCA1* controls; p=0.016). Six of 9 RRSO-related cases were stage I. ROCA flagged 3/6 (50%) incident cases before CA125 exceeded 35U/mL. Eight of 9 stages 0/I/II ovarian cancer patients were alive at last follow-up (median 6 years).

Conclusions: For screened women at familial/genetic ovarian cancer risk, ROCA q3 months had better early-stage sensitivity at high specificity, and low yet possibly acceptable PPV compared with CA125>35 U/mL q6/q12 months, warranting further larger cohort evaluation.

Introduction

Early detection of ovarian cancer with periodic CA125 blood tests and transvaginal ultrasound (TVU) was recommended in the US,(1, 2) but not universally,(3) for women at increased familial risk. Recently, the US recommendation evolved to a consideration(4) including investigational screening studies(5) since standard use of CA125 and TVU showed no screening efficacy(6-12), with most cases detected in late-stage disease.(13, 14) We conducted two pilot detection trials in women at increased familial risk to test a new approach to screening, estimating specificity, positive predictive value (PPV), and comparing the proportion detected in early-stage with the proportion in high-risk historical controls. To increase the proportion detected in early-stage while maintaining high test specificity, the new approach (i) personalized screening by detecting significant rises above each woman's CA125 baseline, (ii) tested CA125 more frequently, and (iii) referred women to TVU only following a positive blood test.

Previous CA125-based screening studies in women at familial risk have shown no improvement in outcomes, perhaps because they: (i) classified tests as positive only when CA125 >35 U/mL; (ii) tested annually; and (iii) tested with concurrent CA125 and TVU, which creates high false-positive rates from frequent TVUs. We addressed the first limitation by leveraging longitudinal CA125 data based on studies indicating that each woman's baseline CA125 level is unique.(15-17) ROCA identifies significant rises above each individual's baseline, personalizing the test and increasing the likelihood of earlier disease detection, ideally before reaching the 35 U/mL threshold.(16) Specificity is maintained by ruling out women with high, stable CA125 values. Further exemplifying the need for a personalized approach we note there are significant differences between the CA125 distributions for post-menopausal (98th percentile=35 U/mL) and pre-menopausal (98th percentile=52 U/mL) women.(18)

Regarding the second limitation, most previous screening studies of increased-risk women evaluated annual testing schedules. Data regarding more frequent testing are limited.(19) Ovarian cancer progression from early- to late-stage disease may be too rapid for annual testing to effectively detect early-stage disease.(20) More frequent blood tests might increase the likelihood of detecting early-stage disease.

Finally, simultaneous testing with CA125 and TVU yields high false-positive rates, primarily due to benign TVU-detected adnexal masses, necessitating many surgeries to identify one true-positive.(21) Preliminary data suggest that using TVU as a secondary test to evaluate abnormal CA125 tests might significantly reduce false-positive rates.(22-26) Thus, our studies included annual TVU for all subjects (standard care during conduct of studies), and interim TVU only to assess abnormal ROCA results.

The two prospective pilot early detection studies reported here screened increased-risk women using CA125-based ROCA every three months, interval TVU only for abnormal ROCA results, and annual screening TVU, per standard care. We use the term "increased-risk" *versus* "high-risk" advisedly, to more accurately reflect participant risk heterogeneity, with a high-risk subset (*BRCA1/2* mutation carriers) and groups at intermediate risk between mutation carriers and the general population (unknown mutation status or mutation-negative/strong family-history-positive subjects). The CGN and GOG studies implemented the same screening protocol and eligibility criteria; US and Australian CA125 testing was done in one centralized research laboratory in each country. Multiple duplicate test samples were analyzed to ensure high inter-lab concordance. Study goals included evaluating compliance with the quarterly CA125 screening schedule and obtaining estimates of ROCA performance characteristics through a pre-planned combined analysis of the two studies.

Performance characteristics listed for the CGN study were sensitivity, specificity, and PPV, for the GOG study were specificity and PPV, while the combined analysis specified goals of achieving a specificity of at least 90% and a PPV of at least 10% (see Supplement). Optimal debulking was added as a study endpoint after study initiation.

Methods

These two studies have been described previously.(18, 27) The primary outcomes were specificity, PPV, and sensitivity for *invasive* ovarian cancer.

Subjects

The Cancer Genetics Network (CGN) initiated the ROCA study (NCT-00039559) to assess ROCA's operating characteristics in women at increased familial/genetic risk of ovarian cancer.(28) Subsequently, two ovarian cancer Specialized Program on Research Excellence (SPORE) sites, two Early Detection Research Network (EDRN) sites, and five independent sites opened the study. Together, 25 sites enrolled 2,359 subjects between 2001 and 2011, yielding 6,979 woman-years of screening (median 2.9 yrs; range 0–10.3 yrs). This seemingly short follow-up median duration actually represents 9 screening episodes; 0 years indicates women who enrolled but were never screened. The low median and wide range of duration are due to several CGN sites having additional internal funds enabling screening to continue for longer periods than the other sites. Eligibility criteria included women from families with a deleterious *BRCA1/2* mutation, and/or multiple ovarian and/or breast cancers in first- or second-degree blood relatives (see Supplement). Women who had previously undergone bilateral oophorectomy (n=278) were eligible for screening for primary peritoneal cancer but were excluded from this analysis. In the CGN study, *BRCA1/2* results available at study initiation were recorded but *BRCA1/2* testing was not performed as part of the study.

The Gynecologic Oncology Group (GOG) initiated the GOG-0199 study (NCT-00043472) as a two-arm, non-randomized observational study of increased-risk women who chose between risk-reducing salpingo-oophorectomy (RRSO) and ROCA-based ovarian cancer screening. GOG-0199 had the same eligibility criteria as the CGN study, except that women without ovaries were ineligible. The GOG screening arm followed the ROCA protocol, enabling data to be combined. The GOG-0199 screening arm enrolled 1,459 evaluable subjects into the screening cohort across 112 sites in the US and Australia between 2003 and 2006,(27) yielding 6,101 woman-years of screening (median 5.0yrs, range 0–6.9yrs). GOG-0199 participants who were *BRCA1/2*-unknown at study enrollment underwent research-based germline mutation testing; *BRCA1/2* mutation status was known to study investigators in 99.6% of participants. All subjects in both studies signed IRB-approved informed consent.

Screening strategy

CA125 tests were scheduled every three months. TVU was performed annually regardless of CA125 results as this was considered standard-of-care for high-risk women. The screening strategy implemented ROCA(29) which individualized the screening test for each woman. For any sequence of CA125 results and test intervals, ROCA calculated the chance (risk) that serum CA125 had a change-point profile which had increased significantly above baseline *versus* a flat profile which varies stably around the baseline (see Supplement). An increased change-point risk raised suspicion for an undetected tumor. All screening decisions regarding ROCA scheduling or more detailed ultrasound or gynecologic evaluation were based on the ROCA risk level, not the most recent CA125 test result. After each new CA125, ROCA risk was re-calculated, adding the current CA125 to all previous results, subject's age and menopausal status, and the subject was re-triaged: normal-risk

women (<1% risk of having ovarian cancer) returned in three months for the next CA125; those with an intermediate risk (1-10%) were referred for TVU; and those with an elevated risk (>10%) received TVU and evaluation by a gynecologic oncologist or study site PI. Consequently, women with above-normal risks were referred to more intensive follow-up, commensurate with their risk score. The updated ROCA resulted in rapid referral of women with CA125 levels rising significantly above their baseline, *including increases within the so-called normal range* (≤35 U/mL), to TVU or TVU with gynecologic oncologist review. This strategy avoided further diagnostic evaluation among women with levels >35 U/mL, but stable compared with their baseline. Thus, the extra information contained in ROCA-interpreted longitudinal CA125 levels potentially increases screening test sensitivity, while retaining the same specificity *versus* a fixed cut-off applied to the last CA125 value.

All US serum CA125 values were measured by the Massachusetts General Hospital Clinical Laboratory Research Core using the Elecsys CA125-II assay (Roche Diagnostics, Indianapolis, IN).

Since randomized trials with an unscreened arm were judged unethical in women at increased familial/genetic risk, this study compared specificity and PPV with standards set in normal risk populations, compared the proportion of cancers detected in early-stage with published historical results from high-risk women,(13, 14) and internally compared ROCA with the single threshold rule of >35 U/mL in our data set. Annual specificity of the ROCA blood test was the proportion of women without ovarian cancer not referred to TVU per year. PPV was the proportion of ovarian cancers amongst women undergoing study-indicated pelvic surgery. Early-stage was defined as FIGO (1988) surgical stages 0/I/II, since the five-year survival rate in unselected ovarian cancer patients is strongly correlated with stage (94%, 91%, 86%, 80%, 76%, 67%, for stages IA, IB, IC, IIA, IIB, IIC, and 45%, 39%, 35%, 18% for stages IIIA, IIIB, IIIC, and IV, respectively). The largest survival drop occurs

between stages IIC and IIIA; most ovarian cancers (66.5%) are detected as late-stage disease (III/IV). A surgical procedure was considered screen-indicated if it was preceded by an intermediate or elevated ROCA test.

Since women with *BRCA1/2* mutations are at very high-risk of ovarian cancer, standard care involves strongly considering RRSO following completion of childbearing and at an age when ovarian cancer risk increases above population risk.(5) Study subjects were permitted to elect RRSO in the absence of worrisome symptoms or a positive screening test *at any time during the study*; 696 subjects in the combined study underwent oophorectomy for any reason while on study. While screening trials for normal-risk women consider the positive predictive value (PPV) – the fraction of ovarian cancers among surgeries following a positive screening test – as the primary efficacy metric, PPV may be less important when a woman at increased risk reaches the point at which standard care recommends RRSO for OC risk management, a practice change which followed two 2005 reports.(30, 31) All CGN subjects were followed for ≥one year after their last screening test with a final questionnaire that ascertained all cancer diagnoses. GOG subjects were planned to undergo 5 years of screening, with cancer outcomes monitored by open-ended annual questionnaires. Invasive ovarian, fallopian tube, or primary peritoneal cancer were the endpoints for this analysis; in aggregate, we designated them "ovarian cancer." Each study had central review of all ovarian surgical specimens(32), including all 501 RRSOs, by central pathologists (CGN: Bell, MGH; Welch, BWH; GOG-0199: Sherman, NCI; Ioffe, U Maryland; Ronnett, Johns Hopkins). Among 696 surgical specimens reviewed, there were two instances (0.3%) – one from each study - in which an ovarian cancer was identified by central review (GOG: Sherman; CGN: Welch) but not by the study site pathologist. For one of these cases, central review interpreted the lesion as a serous tubal intraepithelial carcinoma (STIC), while the site identified high-grade dysplasia.

Statistical Methods

Proportions were compared with standards set from screening normal risk women (specificity, PPV) and historical control reports (sensitivity), using an exact binomial test.(33) Estimates of the proportion of increased-risk women with non-screen-detected early-stage ovarian cancer are difficult to obtain from historical reports. Unlike populations at general risk, there are no registries containing population-based estimates of clinical and pathological features for women at increased risk. Also, there is no standard definition of increased risk, and the understanding of which women are at increased risk has changed over time. Ovarian cancer stage distributions in *BRCA1/2* germline mutation carriers are a reasonable surrogate for stage distribution in women at increased risk. For comparison with the results in the two screening studies, the population value of the proportion of early-stage invasive ovarian cancers amongst *BRCA1* carriers was 10%, calculated from the weighted combination of 8%(n=88) and 14%(n=50) from two pathology series reported before screening was common(13, 14). Screening studies of women at increased risk(34) differ in their definitions of "increased risk" and/or in their screening regimen, so it is difficult to aggregate their results. We used stage distribution of unselected normal-risk ovarian cancer patients as an additional comparison, ascertained *via* SEER 9 2001 tumor registry data, in which the proportion of early-stage disease was 33.5%, with SEER stages "local" and "regional" corresponding to FIGO stages I & II.

Results

Study Population Characteristics

Table 1 summarizes race and ethnicity, and Table 2 provides ovarian cancer risk factors at baseline. Among 3,449 eligible subjects, 41% had prior breast cancer, 83% had a breast cancer family history

(34% included one or more premenopausal breast cancers), 47% had an ovarian cancer family history, and 34% reported a family history of both. Most subjects were white (92%), and 20% were of Ashkenazi Jewish descent. More than half (59%) were premenopausal, 80% were parous, 10% had a pre-enrollment hysterectomy; by self-report, 77% had used oral contraceptives (median=5 years; range 0–52), and 30% had used hormone replacement therapy (median=3 years; range 0–44). The CGN cohort comprised 58% of participants, contributing 6,979 woman-years of screening (53%), while the GOG cohort contributed 6,101 years of screening. Twenty percent of CGN study participants reported a deleterious mutation. The probability of carrying a *BRCA1/2* mutation was estimated using *BRCAPRO*(35) for the CGN cohort, yielding an average of 21%, indicating that reporters of *BRCA* mutation status were likely representative of the whole CGN cohort. In screening subjects from GOG-0199, 20% had a documented positive *BRCA1/2* test. The similarity in mutation prevalence between the two study cohorts suggests that the common eligibility criteria yielded study groups of equivalent genetic risk. The distribution of variables in Table 1 was similar in both study populations.

Table 1 about here

Screening Results

Supplementary Table 1 lists the number of subjects by year for which ROCA was used to evaluate CA125 profiles and triage by risk. On average, 92% of ROCA evaluations indicated a normal risk (for the study population); these subjects returned for their next regularly scheduled test. Less than 7% had an intermediate risk and were referred for a study-indicated TVU (92% annual specificity *vs* 90%, p=0.0001), while 1% of ROCA tests had an elevated risk level, and were referred to TVU and evaluation by a gynecologic oncologist or study PI (99% annual specificity). Based on screening model characteristics, we had estimated that 1-2% of ROCA assays would recommend the highest level of intervention, a rate that was achieved.

The high frequency of CA125 testing was a crucial screening trial element; we hypothesized that increased frequency would improve detecting early-stage ovarian cancer. The protocol-specified ROCA testing frequency was every three months *(i.e.,* four times/year). The average actual testing frequency (ratio of total CA125 tests to total screening years) was one every four months (three times/year). Each subsequent CA125 test was scheduled three months from last test date if risk was normal, or three months from normal ultrasound date if the risk was intermediate or elevated. Despite the high frequency of testing, 88% of CA125 tests were conducted within one month of their scheduled time, demonstrating a very high screening compliance rate.

Cancer Outcomes (Sensitivity)

Table 2 lists the 19 malignant ovarian neoplasms (18 invasive and one intraepithelial carcinoma) identified during the two screening studies: ovary=8, fallopian tube=6 (including 1 serous tubal intraepithelial carcinoma (STIC)), ovary+fallopian tube=3, primary peritoneal carcinoma=2. Eleven of 15 serous cancers were high-grade. Three low malignant potential (LMP) tumors, one each in incident, elective RRSO, and prevalent subgroups, were identified, all in stage I; none were known to have a *BRCA* mutation. The LMPs were omitted from all subsequent analyses. The proportion of study-detected ovarian cancers in early-stage (stages 0/I/II), ROCA detection prior to CA125 >35 U/mL, and optimal debulking defined the outcomes potentially positively affected by early detection. Screening would not be expected to modify stage at detection of a large proportion of existing but currently undetected tumors, *i.e.*, among prevalent cases (first study-related CA125 test was elevated or part of a rising pattern).(36) Effective screening for incident cases, which arose during rather than before screening initiation, would be expected to yield an increased proportion of early-stage cases. Nine women were diagnosed with ovarian cancers at elective RRSO (none of their screening tests

had produced a surgical recommendation); thus, we separated surgically-detected cases from screen-detected cases. We analyzed our data stratified by incident, elective RRSO, and prevalent cancer diagnoses. Of 19 ovarian carcinomas identified, six were incident, nine elective RRSO, and four prevalent cases. All prevalent cases were ROCA screen-detected and positive by CA125>35U/mL rule. None of the four prevalent invasive cases was early-stage, statistically commensurate with the historical rate of 10% early stage disease in high-risk women. Two stage IV prevalent cases were not optimally debulked. Six (67%) of the nine RRSO-related carcinoma cases were early-stage, including one non-invasive STIC (Stage 0). All RRSO patients with clinically occult cancers were optimally debulked.

The six incident cases reflect long-term screening program outcomes; five were screen-detected and one was clinically-detected. Three of the six incident cancers were screen-detected in early-stage (50%; 95%CI=12%-88%; 50% *versus* 10% historical *BRCA1* cases, *p*=0.016; 50% *versus* 33.5% normal risk cases, p>0.10). Of the 3 early-stage invasive incident cases, two had a *BRCA1* mutation, and one had both *BRCA1* and *BRCA2* mutations. The two late-stage (IIIC) cases were *BRCA1/2* mutation-negative. Of the 3 early-stage cases, two were identified when the last CA125 was still <35 U/mL. In 3/6 cases (50%), ROCA signaled intervention (TVU or TVU plus gynecologic oncologist consultation) prior to CA125 >35 U/mL. All 6 incident cases were optimally debulked. Eight of 9 women with stages 0/I/II ovarian cancers detected in this study were alive at last known follow-up (range 5-9yrs), including the patient with STIC, who is alive and disease-free 5 years after surgery. Of the 3 ROCA-detected stages I/II cases, all were alive at follow-up, 2 at 8 years and one at 6 years.

Table 2 about here

696 subjects had ovarian surgery during the course of study, of whom 195 had surgery preceded by an intermediate or elevated ROCA. Of those surgeries, 9 had ovarian cancer, yielding a conservative

PPV of 4.6% (95%CI=2.1–8.6%). Among the 186 false-positive surgeries following a non-normal ROCA, the median age was 48 years. Among the 501 elective RRSOs, there were 9 ovarian cancer cases, yielding an incidence of 2% (95%CI=0.8–3.4%).

Figure 1 illustrates how longitudinal ROCA testing detected a stage IIB ovarian cancer despite CA125 remaining <35 U/mL (red line). ROCA interpreted the CA125 level at the last 2 tests (red circles) as significantly above this woman's baseline, resulting in referral to ultrasound. The second ultrasound was abnormal, which generated a surgical recommendation and diagnosis of a stage IIB ovarian cancer, which was optimally debulked.

Figure 1 about here

Discussion

This study shows that ROCA-driven q3 months CA125 testing among increased-risk women was associated with a high specificity >90% and a low but possibly acceptable PPV <10%. This strategy yielded an increased proportion of early-stage invasive ovarian cancer among incident cases compared with historical invasive *BRCA1* cases (50% *versus* 10%; p=0.016) and compared with cases from the general population (50% *versus* 33.5%; p>0.10) though not significantly. We have focused sensitivity analysis and discussion on this study sub-group because outcomes for incident cases comprise the best metric for long-term screening. ROCA detected 5/6 (83%) incident cases, with three (50%) of the 6 detected prior to CA125 exceeding the standard cut-point of 35 U/mL. These results are commensurate with recent data from the UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) general population trial,(36) in which 50% of incident cases were also detected by ROCA, based on annual CA125 testing prior to CA125 >35 U/mL, and 89% of incident cases were screen-detected.(36) The efficient use of longitudinal CA125 information, with half of the incident cases detected by ROCA prior to CA125 exceeding the standard cut-point, the 3-month

frequency of scheduled CA125 tests, and using TVU only to triage women with abnormal ROCA results, represent the innovations in the current screening strategy which resulted in a significantly higher proportion of early-stage cases detected in this combined analysis of two screening trials compared with historical *BRCA1* controls.

ROCA quantitatively assessed whether recent CA125 results were significantly elevated above each woman's baseline. Figure 1 illustrates a change-point at year 3.5, with a steady increase in five subsequent CA125 tests. In contrast, under the screening rule based on >35 U/mL cut-off, no ultrasound would have been performed until after year 6, by which time the ovarian cancer might have progressed to a more advanced stage. In addition to personalizing the test, our results were obtained using CA125 testing scheduled every 3 months, twice the maximum frequency of CA125 testing that was considered under standard care for increased-risk women.(4) Consequently, 9/10 non-RRSO-related invasive cancers were screen-detected, with only one clinically-detected case (an additional 9 were RRSO-detected), and 17/19 (89%; 95%CI 67%, 99%) cancer patients were optimally debulked; only the two prevalent stage IV cases were not optimally debulked. This compares with 58% optimally debulked in the unscreened normal-risk population (weighted average from Cochrane Collaboration Report, Table 1: Studies post-2001).(37) Since optimal debulking has been shown to increase survival significantly,(37, 38) this may be an additional beneficial outcome for ROCA q3 months screening.

Despite early predictions that women would not comply with testing every three months, a very high proportion (88%) of CA125 tests was obtained within one month of their scheduled phlebotomy date. On average, our increased-risk study participants underwent CA125 testing every 4 months. These very high compliance rates are encouraging, as they demonstrate the clinical feasibility of this

intensive strategy, and likely reflect the fact that increased-risk women who choose to retain their ovaries and enroll in a screening trial are very highly motivated to adhere to screening recommendations.

Our study has limitations. Lacking an unscreened control group to which ROCA participants can be compared comprises a significant methodological limitation, but at the time this study was initiated it was judged ethically unacceptable since combined CA125/TVU screening had become the *de facto* standard of care for increased-risk women, despite unproven efficacy. This represents a difficult methodological constraint: it is unlikely that a prospective, randomized screening trial will be performed in increased-risk women, despite universal recognition that such a design is required to assess disease-specific mortality reduction, the gold-standard screening endpoint. Therefore, stage at detection compared with historical controls was used as a surrogate comparison. However, detecting 3/6 incident carcinoma cases in early-stage does not prove that these women will live longer. UKCTOCS was a randomized screening trial,(25) but it implemented *annual* ROCA-based CA125 screening in *only normal-risk women*; its results will only indirectly be related to assessing q3 months ROCA in high-risk women. Our study complements the UKCTOCS report by providing results on increased-risk women. Additional data regarding screen-detected incident cases from ROCA screening of increased-risk populations are needed before our finding of an increase in the proportion of early-stage cases is conclusive. Further studies will also help determine whether interpreting CA125 values with ROCA or the higher q3 months frequency of CA125 testing or both modifications of standard CA125 screening are responsible for the increase in early-stage detection.

A second caveat follows from the low power of our primary analysis, since it is based on only five incident invasive ovarian cancers. But nine additional cancers were detected among women who

elected RRSO in the absence of symptoms or a ROCA-based recommendation for surgery. Had that option not been available to study participants, the number of analyzable incident events would have been meaningfully larger. We had estimated that >20 ovarian cancers would develop in this genetically-predisposed population of women, but the anticipated increased statistical power relative to studying general population subjects was reduced significantly because 14.5% (501/3,448) of participants elected RRSO without a screening-related surgical recommendation, since it is standard practice to counsel genetically at-risk women to consider RRSO once childbearing has been completed and at an age when ovarian cancer risk increases above population risk. Furthermore, when these protocols were designed, *BRCA*-negative women with only breast cancer in their family were study-eligible due to their hypothesized increased risk of ovarian cancer. These women are now not anticipated to be at substantially increased ovarian cancer risk,(30, 39) thus further reducing the anticipated power of the study. We are exploring opportunities to pool our results with those of other ROCA-based ovarian cancer screening trials, such as the UK Familial Ovarian Cancer Screening Study (UKFOCSS),(12) in an effort to increase statistical power for sensitivity and PPV.

RRSO cases also present an interpretation issue for screening sensitivity. An alternative interpretation of our data is that the RRSO cases were missed by ROCA, and therefore the sensitivity for early-stage disease for incident cases was 29% (4/14 = 5 incident ROCA-detected cases + 9 cases detected on RRSO) – that is, ROCA missed all 9 RRSO cases (3–25 weeks from last CA125 test to surgery, median 9.3). However, the aim of early detection is to diagnose cancers in early-stage disease, ideally stages 0/I. If the RRSO cases comprised all late-stage disease, then the interpretation that ROCA missed these cases would be reasonable but, in fact, 6/9 RRSO cases were early-stage cancers. RRSO "censored" these cases before they reached late-stage disease. Another analytic alternative would be to combine RRSO cases with incident cases to estimate the proportion

identified during the screening trial in early-stage disease. This interpretation combines 3/6 incident cases with 6/9 RRSO cases for a combined early-stage proportion of 60% (9/15; 95%CI: 32%-84%), even higher than the estimate based on incident cases alone (50%), yields a much tighter confidence interval and therefore greater statistical significance. Thus, we judge our decision to restrict the early-stage estimate to only incident cases as conservative and appropriate.

Another reason we analyzed the RRSO cases separately was because a secondary sensitivity outcome compares ROCA to a CA125 threshold and the RRSO action censored these cases prior to either ROCA being positive or CA125 exceeding 35U/mL, thus providing no information regarding which occurred first. The large proportion of early-stage cancers among the RRSO cases provides further encouragement to considering RRSO in this population, and reason to hope that some of these women will become long-term, disease-free survivors.

The low (5%) screening-related positive predictive value indicates that twenty surgical procedures were performed for each ovarian cancer detected, and comprises a limitation that warrants special comment. We believe this estimate may nonetheless be acceptable among *BRCA1/2* mutation carriers after they complete childbearing and reach the age at which RRSO is regarded as standard of care, yet who chose to continue screening. The PPV standard set from consideration of screening trials in the general population is not appropriate in a population for which RRSO is strongly recommended and widely practiced. The low PPV does require caution for women with false-positive results who are below the age at which RRSO is recommended among *BRCA1/2* carriers or who have not completed child bearing. Thus, it is reassuring that the median age among false-positive cases was 47 years.

Due to incomplete *BRCA* mutation ascertainment in the CGN cohort (a budgetary constraint), our data do not permit drawing conclusions about the utility of this screening strategy in women from mutation-negative/strong family history kindreds. However, among the 19 cancers, there were 13 *BRCA1*, 1 *BRCA2*, and 1 subject with a mutation in both genes; 3 were *BRCA1/2* negative; and 1 subject was untested. Thus, limiting frequent ROCA screening to *BRCA* mutation carriers would still miss some cases (3/18=17% of cases tested) in this increased-risk cohort.

Another caveat is that real world application would require adjusting for CA125 variation between laboratories, a concern mitigated by very high inter-laboratory correlation.(40) A further limitation: ROCA screening, even in high-risk populations, requires screening many women to detect a few early-stage cases. In the combined studies, 3 early-stage invasive incident cases were detected that may have been clinically detected in late-stage without screening in 13,080 woman-years, *i.e.* 23 early-stage cases per 100,000 screened women (0.023%), a crucial input for a future cost-benefit assessment.

Finally, while ROCA detected cases in an earlier stage than screening with a single CA125 >35U/mL in this study, all were detected in stage II (IIA,IIA,IIB), which has much better survival than stages III/IV, but significantly lower survival than stage I. Better blood tests and secondary imaging must be developed to detect cases in stages 0/I. Many high-grade serous ovarian cancers in *BRCA1/2* carriers are believed to originate in the distal fimbriated end of the fallopian tube,(41) and proteins secreted by fallopian tube epithelium may provide promising biomarker candidates.(42) TVU was negative in 3/6 prevalent and 2/5 incident cases, consonant with fallopian tubes being difficult to visualize with TVU and suggesting that a better imaging test is required. The CA125 protein is not shed by 20% of ovarian cancers, so a CA125-based ROCA cannot detect such cancers. Developing

a biomarker panel which covers the full ovarian cancer spectrum, and interpreting those data with longitudinal, ROCA-like models, might improve the performance of screening programs aimed at detecting early-stage disease, as shown with FDA-authorized multiple marker diagnostic tests for pelvic masses (ROMA, OVA1).(43, 44) Approaches that may enable earlier detection through analysis of DNA in lower genital tract samples are also under investigation.(45, 46)

In summary, our study provides the following encouraging evidence: (1) women at increased-risk who agree to an intensive screening regimen are compliant; (2) more frequent CA125 testing interpreted by ROCA is associated with a high specificity and a significant increase in the detection of early-stage incident ovarian cancer compared with published data from historical controls; (3) ROCA detected 50% of incident cases prior to the standard cut-point of 35 U/mL; (4) ROCA detection is associated with a high optimal debulking rate in incident cases; and (5) 8 of 9 women with early-stage cancer were alive at last follow-up. Importantly, we believe these observations do not represent a sufficient basis for introducing this screening strategy into clinical practice *as an alternative to RRSO*. While even the mixed evidence on the effectiveness of ovarian cancer screening is welcome news,(36, 47) we still regard consideration of RRSO upon completion of childbearing and reaching the recommended age as the current standard of care for *BRCA1/2* mutation carriers. It is essential to recall that even an effective screening program cannot reduce the risk of *developing* ovarian cancer; its benefit can only derive from earlier detection and improved survival. However, there still remains a significant subset of increased-risk women who choose to retain their ovaries and tubes once their families are complete, despite being fully informed of the benefits of RRSO, including significantly reduced risks of both ovarian cancer and breast cancer, and significantly improved overall survival.(48) Our data suggest that for women who choose screening instead of RRSO, ROCA screening with quarterly CA125 tests, plus TVU as a secondary screen for those with an elevated risk

score, appeared to be a significant improvement over q6-12 monthly CA125 screening with a single cut-point, such as 35 U/mL. However, due to the small number of incident cases, further evidence from larger cohorts is required before ROCA with q3 months screening tests can be confidently recommended as a replacement for annual or six-monthly testing for women choosing screening.

Most importantly, the CGN study and GOG-0199 study would not have been possible without the selfless contributions of the 2,359 (CGN) and 2,605 (GOG) women at increased risk who enrolled in these time-intensive studies.

Abbreviations:
Dx: diagnosis
ROCA +ve: ROCA recommended surgical evaluation.
ROCA vs >35: was ROCA abnormal prior to CA125 exceeding 35 U/mL?
     B: ROCA abnormal before CA125 exceeded 35 U/mL
     =: ROCA became abnormal and CA125 exceeded 35 U/mL simultaneously
     A: ROCA became abnormal after CA125 exceeded 35 U/mL
TVU: transvaginal ultrasound
Opt Debulk: patient optimally-debulked
Stg: FIGO stage
Grd: histologic grade
Neg: negative
Pos: positive
NA: not available – ovaries not visualized on TVU
RRSO: risk-reducing salpingo-oophorectomy
* WHO classification divides serous carcinoma into two categories (LG, HG), but WHO classification was not available at the time of pathology review. All Grade 3 serous carcinomas would be HG by WHO.

LEGENDS

Figure 1: Early detection of ovarian cancer via ROCA even though CA125 remains below 35 U/mL. The consistent increase in CA125 from the nadir (blue arrow) increases the calculated risk of having ovarian cancer with each additional CA125 test until the risk is elevated (red circles) with a recommendation of a trans-vaginal ultrasound. Surgery was recommended at the second ultrasound and a mixed endometrioid and serous ovarian cancer (stage IIB) detected.
