

## Rationale

In order for downstream product generation to proceed, the science team needs to know when downstream processing can begin. Depending on where we are in the mission, turnaround times vary from days to weeks. We expect an initial assessment of Level-2 data 36 hours after data are downlinked, following the procedures documented here. The initial "bless request" can simply as something like "as planned" if the steps documented here are followed with no major problems, or with additional comments in the request if needed.

The reconstructed pointing information may not yet be available at the time this approval is done [hmm, this may be a problem, let's discuss].

### OCAMS Review and Approval Process:

The OCAMS review and approval process is baselined to the calibration process outlined in the OCAMS calibration PDS document: [ocams\\_calibration\\_description\\_v1.5.pdf](#). The raw signal from L0 is dark-subtracted, flat-fielded and charge-smear-corrected by the approved process (Level 1). Validation of this step is accomplished by downloading image headers for all images which contain the names of the BiasDark (BD) and Flat Field (FF) files used in the processing. This process is checked (off-line) against a master list of BiasDarks and Flats. A result flag is set to 1 when customized calibration files are used and 0 if not. A value of 0 results whenever an expected BD file was not created because the dark was missing (for whatever reason). In that case, the pipeline defaults to a standard dark processing step. This behavior is nominal.

The L1 result is then divided by the exposure time and the result scaled to produce 3 Level 2 products: 1) L2frac: signal rate scaled by the responsivity to solar light from 250 to 1100 nm; 2) L2rad: signal rate scaled by responsivity to solar light over the waveband of the filter (see precise radiance and spectral radiance responsivities in calibration document) producing spectrally integrated radiances for the panchromatic filter and spectrally resolved radiances for the narrower color filters and 3) L2iof: signal rate from L2rad scaled to target's range to Sun in AU<sup>2</sup> and normalized by the waveband of the filter (see precise waveband magnitudes in calibration document).

To validate the pipeline approach, a parallel pipeline is run that reproduces the above calibration result to within a signal level equivalent to the noise floor for the cameras (~10 DN).

Known variances of the current calibration pipeline include:

1) the use of the Sun--Spacecraft Distance instead of Sun-Bennu distance when deriving the I/F and other L2 radiometric products [errors incurred are negligible throughout the vast majority of the mission.]

2) mis-selection of appropriate BiasDarks for very short exposure time images (1-2 msec) because of incorrect usage of commanded exposure time versus actual exposure time identifier.

ocams\_calibration\_description\_v1.5.pdf

OVIRS Review and Approval Process:

First quick look approval will involve:

pulling L2 science data from spocflight, confirming format, and general data quality (i.e., does it roughly look like a target spectrum?)

pulling L2 trending data (stand-alone calibration blocks) from spocflight, to look for major performance changes

At this level, it will not include detailed review of:

calibration accuracy

data quality of each spectrum

pointing accuracy

Later review will confirm the absolute calibration accuracy, etc., and make require diagnostics and/or a rerun of the pipeline calibration. Users of Level 2 products should stay alert for notifications of a reprocessing.

L3b validation:

Pull L3a and L3b from SPOCFLIGHT

Run L3a through local thermal tail code

Check the output against the actual L3b product to make sure they agree

Plot several of the L3b spectra and make sure they look reasonable

significant drop-off at long wavelengths may indicate overcorrection, whereas a significant increase may indicate under correction

Check derived temperatures and emissivities to make sure they are reasonable

note that the emissivity here is more of a scaling factor than a physical emissivity, so the values can be farther from 1 than emissivities normally would be. But negative values, values  $<0.1$ , and values much larger than 1 could indicate some issues

Temperatures are expected to fall between 150 and 500 K

## **Calibration Description: OSIRIS-REx Camera Suite (OCAMS)**

**Dathon Golish and Bashar Rizk, April 1, 2018 – Version 1.0**

**Revised May 23, 2018 – Version 1.1**

**Revised June 4, 2018 – Version 1.2**

**Revised July 2, 2018 – Version 1.3**

**Revised September 4, 2018 – Version 1.4**

**Revised October 31, 2018 – Version 1.5**

### **Acronym List**

CCD	Charge Coupled Device
DA	Detector Assembly
DN	Digital Number
FITS	Flexible Image Transport System
FM	Flight Model
FPA	Focal Plane Array
IDL	Interactive Data Language
L0	Level 0
L1	Level 1
L2	Level 2
MATLAB	Matrix Laboratory
OCAMS	OSIRIS-Rex Camera Suite
PDS	Planetary Data System
PTC	Photon Transfer Curve
RCC	Radiometric Calibration Constant
SIS	Software Interface Specification
SNR	Signal to Noise Ratio
SPOC	Science Processing and Operations Center
TVAC	Thermal Vacuum
UUT	Unit Under Test

### **Nominal OCAMS Calibration**

OCAMS images acquired in flight and provided through the PDS experience several processing steps that convert the raw signal recorded in DN by the instruments in flight to the signal archived by the data repository. They begin life as electronically shuttered images recorded during the mission as individual electrons that correspond to the solar photons reflected from the surface of the Bennu, the Earth, the Moon, the planets and main-belt asteroids or as stellar photons from any of several thousand distant stars.

These processing steps are described below within individual sections. In summary they consist of bias/dark subtraction, charge-smear correction, flat-field normalization to convert the raw L0 images transmitted from the spacecraft and provided by the ground data system to L1 FITS files. Radiometric calibration converts L1 files into several different flavors of L2 (Figure 1), including a radiance (Rad), a spectral radiance (Spec Rad) and a reflectance (I/F) product. Versioning of the OCAMS pipeline is recorded in each image label in the Mission\_area data\_processing\_information class ocams\_pl\_ver attribute.

The comments in this summary document are largely based on these sources. More extensive descriptions will be provided when the OCAMS team publishes the calibration of the OCAMS instruments, a process that is still on-going.

### **Bias (1112x1044 array size)**

Bias subtraction is intended to remove the fixed offset applied by the readout electronics. A bias subtracted image (in the absence of dark or optically generated current) should have a mean value of 0.

Bias subtraction is applied in the following way:

A master bias file (1112x1044) is created from bias images taken either on the ground or coincident with the images being corrected. The master bias file used is recorded in the reference list section of the data product label. The algorithm performs pixel-wise subtraction (e.g. a straight array subtraction) of the master bias file (*Bias*) from the image being processed (*Raw*), as shown in Equation 1.

$$Tmp_{ij} = Raw_{ij} - Bias_{ij} \quad (1)$$

After subtracting the master bias, to account for bias variations at the moment of acquisition, overscan columns are used to update the bias correction. The overscan columns are not physical pixels; they are empty reads of the readout electronics, which should contain only the bias offset plus read noise. The overscan columns are the last 16 columns read out by the detector. The overscan columns having been corrected by Equation 1, the master bias, so any residual signal should be the in-situ bias variation. To correct for the in-situ variation, the 16 overscan columns (see Figure 1) are averaged on a row-wise basis and then the column vector of the averaged results is box-car smoothed<sup>1</sup>. The size of the kernel is user controllable, but the default is 51 pixels. This large default is chosen to smooth the impact of extended cosmic ray hits that can cover several pixels. Although cosmic ray hits cannot affect the overscan columns, this operation is kept consistent with the Dark and Bias/Dark algorithms (which can be affected by cosmic rays). The smoothed result is subtracted on a row-wise basis, as shown in Equations 2-4.

$$overscan_i = \sum_{j=1096}^{1111} \frac{Tmp_{ij}}{16} \quad (2)$$

$$\overrightarrow{overscan'} = \text{boxcar}(\overrightarrow{overscan}, 51) \quad (3)$$

$$\overrightarrow{Corrected}_i = \overrightarrow{Tmp}_i - \overrightarrow{overscan'} \quad (4)$$

---

<sup>1</sup> The standard IDL function SMOOTH is applied, using the EDGE\_TRUNCATE option. The IDL SMOOTH function returns a copy of the input array smoothed with a boxcar average of the specified full width

$$W = \begin{cases} width & \text{if width is odd} \\ width + 1 & \text{otherwise} \end{cases}$$

We use the “EDGE\_TRUNCATE” option, under which the edge pixels are assumed to be replicated as many times as necessary to complete the boxcar. The equation is thus:

$$R_i = \frac{1}{W} \sum_{j=0}^{W-1} A_{i+j-\text{floor}(\frac{W}{2})}$$

Where  $A_k$  is taken as the edge pixel  $A_0$  or  $A_{N-1}$  if the subscript quantity  $k = i + j - \text{floor}(\frac{W}{2})$  is  $< 0$  or  $> N - 1$ , respectively

### **Dark (1112x1044 array size)**

Dark subtraction removes the signal generated not by photons, but by phonons, thermal excitations in the detector material. Dark signal is removed in a way similar to bias signal:

A master dark file (1112x1044) is created from dark images taken coincident with the images being corrected. The master dark file used is recorded in the reference list section of the data product label. The algorithm performs pixel-wise subtraction (e.g. a straight array subtraction) of the master dark file (*Dark*) from the image being processed (*Raw*), as shown in Equation 5. The advantage to this method is that it corrects pixel-to-pixel variation in the dark current, which can vary across the detector. Note that the input to this process has likely been bias corrected, but is referred to here as *Raw*, without that assumption.

$$Tmp_{ij} = Raw_{ij} - Dark_{ij} \quad (5)$$

After subtracting the master dark, to account for dark current variations at the moment of acquisition, covered columns are used to update the dark correction. There are 24 covered columns on either side of the active region (48 columns total, indicated in blue on Figure 1). The covered columns are averaged on a row-wise basis. The covered columns have themselves been corrected by the master dark; any residual signal in those columns represent instantaneous dark current variation. To correct for that variation, the 48 covered columns are averaged on a row-wise basis and then the column vector of the averaged results is box-car smoothed as with bias correction. The smoothed result is subtracted on a row-wise basis, as shown in Equations 6-8.

$$covered_i = \frac{(\sum_{j=0}^{23} Tmp_{ij} + \sum_{j=1056}^{1079} Tmp_{ij})}{48} \quad (6)$$

$$\overrightarrow{covered}' = \text{boxcar}(\overrightarrow{covered}, 51) \quad (7)$$

$$\overrightarrow{Corrected}'_i = \overrightarrow{Tmp}_i - \overrightarrow{covered}' \quad (8)$$

### **Bias + Dark (1112x1044 array size)**

For the majority of the OCAMS images taken in flight, even star fields, bias levels have dominated the dark current, which is measurable but rather inconsequential. As a result, the bias + dark correction can be conveniently and effectively applied together. The master bias+dark files (1112x1044) are tagged with the time period and exposure time for which they are relevant and used to process images acquired within that period and with identical exposure times. Subtraction of the BiasDark master and then update via the covered columns using Equations 6 -8 (which contain both residual bias and dark signal) are performed in the same way as with biases and darks individually.

### **Charge Smear**

Charge smear is the result of signal being generated when exposed to light during the frame transfer of pixel wells both on and off the active area. It is most noticeable when a very bright object, whether point source or extended source, is resident within the camera's field of view, requiring a very short exposure time. The exposure time is short enough to be comparable to the time required to clock the pixels on and off the array. As a result, an extended line is recorded above and below the bright source, marking the charge collected by each of these pixels as a bright object's image is trailed across them. In order to be radiometrically accurate, removing charge smear signal requires reducing the effective exposure time of the image. This effective exposure time (found in the L1 reduced image product in the `effective_exposure` attribute), calculated as the actual exposure time subtracted by the frame transfer time (1.044 ms) is tracked in the header (`EXPEFF`) of the FITS file and used directly by the radiometric corrections later in the pipeline.

The signal recorded by the detector due to the full imaging operation (exposure time and frame transfer time) can be measured by summing the signal on a column-wise basis. This sum is the full amount of charge accumulated. A fraction of that charge (the ratio of the row transfer time to the integration time) will be distributed to each pixel in the column. A first order correction for charge smear is to subtract that fraction of the total signal off of every pixel in a given column. However, this correction is an overestimate because it includes the signal generated by charge smear itself. We can solve for the true amount of charge smear in the following way. The total signal measured by a given pixel is the combination of the true signal from its location in the scene and the charge smear from locations above and below it.

$$\mathbf{S} = \widehat{\mathbf{S}} + \mathbf{E} \quad (6)$$

where  $\mathbf{S}$  is the measured signal,  $\widehat{\mathbf{S}}$  is the actual signal, and  $\mathbf{E}$  is the contribution from charge smear. For pixel  $(i,j)$ , the charge smear contribution is proportional to the sum of the actual signals in that column.

$$s_{i,j} = \widehat{s}_{i,j} + \epsilon \sum_i \widehat{s}_j$$

where  $(i,j)$  is the (row, column) of the pixel location and  $\epsilon$  is the ratio of row transfer time to exposure time (i.e. how long each pixel is exposed to the other locations in the scene as the frame is transferred). The signal measured in a column is then the sum of all pixels in that column.

$$\sum_i s_j = \sum_i \left( \widehat{s}_{i,j} + \epsilon \sum_i \widehat{s}_j \right)$$

$\sum_i s_j$  is the sum of the  $j^{\text{th}}$  column in the image. It is an input to the solution, so will be represented as the variable  $\mathbf{Y}$ . We substitute this in, as well as substituting  $\widehat{\mathbf{S}} = \mathbf{S} - \mathbf{E}$ .

$$Y_j = \sum_i \left( (s_j - E_j) + \epsilon \sum_i (s_j - E_j) \right)$$

Again we can substitute the measured signal in the column,  $\mathbf{Y}$ .

$$Y_j = \sum_i \left( s_j - E_j + \epsilon Y_j - \epsilon \sum_i E_j \right)$$

The sum of the charge smear term over the column is merely the charge smear term, summed  $N_{row}$  times (the number of rows, 1044).

$$\sum E = N_{row} * E$$

We can therefore substitute further and distribute the summing operation.

$$Y_j = \sum_i s_j - \sum_i E_j + \sum_i \epsilon Y_j - N_{row} * \epsilon \sum_i E_j$$

$$Y_j = Y_j - N_{row} * E_j + N_{row} * \epsilon * Y_j - N_{row}^2 * \epsilon * E_j$$

Finally, we can solve for the charge smear term, which will convert the measured signal of any pixel in the  $j^{th}$  column to the actual signal.

$$E_j = \frac{\epsilon Y_j}{N_{row} \epsilon + 1}$$

In practice, we have seen that this term does not perfectly correct charge smear. To improve the correction, we use the covered rows to evaluate the residual. If the above algorithm perfectly predicted charge smear, the covered rows would have a mean signal of zero (assuming bias and dark signals have already been removed). Mean signal above or below zero in the covered rows indicate under- or over-correction in the charge smear algorithm. We can therefore modify the magnitude of the correction in the appropriate direction and repeat. This continues iteratively until the mean signal in the covered row region is minimized. This method is less susceptible to the small number of covered rows, because we can average all the columns together to improve our statistics. The iterative predicted algorithm leads to near complete removal of charge smear.

For EGA images, an alternative charge smear correction method was necessary due to the very short exposure times (see the ‘Icicles’ caveat). One of two methods are used, both of which require user intervention to choose a portion of the image to use to generate the correction. In the ‘guided’ method, the user provides the row and column values for the four corners of a rectangle that contain only charge smear (i.e. off the limb of the Earth/Moon, looking at dark sky). The median (along the columns) of the pixels within that rectangle are used to create a correction vector that is subtracted off of the entire image. Columns outside the rectangle will have a correction of zero. The ‘in-situ’ method is used for EGA images that do not have any dark sky in the image. The user provides the starting and ending columns (the row values are ignored and can be provided as zeros) of a region of the image that has a relatively uniform scene (i.e. uniform clouds). The intention is that the variation in this uniform region is representative of charge smear and can be used to generate a correction. Clearly this method can only be as effective as the uniformity of the background, but there are some EGA images for which this is the only option. The median of the rows indicated by the column limits is calculated to create a column-wise charge smear correction. The methods and values used for EGA images are provided in the table below.

**Table 1 EGA Charge Smear Correction Settings**

### **Flat Field (1024x1024 array size)**

Flat field corrects for the spatial variation in optical responsivity across the detector itself. It can account for both slowly varying and rapidly-varying (pixel-to-pixel) relative responsivities. It is currently only corrected by applying a master flat field acquired on the ground. The master flat field (1024x1024) used is indicated in the data product label reference list. The master flat field is calculated as the inverse of the system response to a spatially uniform scene. Therefore, the master flat field (*Flat*) is applied by multiplying it against the image to be corrected (*Raw*), as shown in Equation 9. Note that the input to this process has likely been bias/dark corrected, but is referred to here as *Raw*, without that assumption.

$$Corrected_{ij} = Raw_{ij} * Flat_{ij} \quad (9)$$

### **Laboratory Radiometric Calibration to Radiance (Rad 250-1100 nm) (1024x1024 array size)**

Radiometric calibration to radiance converts the signal rate in DN/sec between 250 and 1100 nm to the radiance of the detected field in  $W\ m^{-2}\ sr^{-1}$  by applying radiometric calibration constants determined on the ground. These conversions were used for laboratory calibrations during ground testing. These constants are

expressed in terms of signal, per second, per unit of radiance. Therefore, to convert to radiance, the measured signal ( $DN$ ) is divided by the radiometric calibration constant ( $RCC$ ) and by the effective exposure time ( $t_{exp}$ ) of the image, as shown in Equation 10. The effective exposure time, as described in the Charge Smear section, is recorded in milliseconds. However the  $RCC$  is calculated in terms of seconds, so the effective exposure time must be converted to seconds before use in Equation 10. The  $RCC$  is temperature-dependent, so is scaled based on the temperature of the CCD at the time of image acquisition.

$$Radiance_{ij} = \frac{\left(\frac{DN_{ij}}{t_{exp}}\right)}{RCC} \quad (10)$$

**Table 2 OCAMS Radiance Responsivities to reflected solar light between 250 and 1100 nm in (DN/sec) / (Wm<sup>-2</sup>sr<sup>-1</sup>)**

SamCam	Pan 1	Pan 4	Pan 5	Diopter		
	150829	152679	151077	153902		

**Radiometric Calibration to Radiance (1024x1024 array size)**

For the panchromatic filters, radiometric calibration to radiance converts the signal rate in DN/sec to radiance detected in W m<sup>-2</sup> sr<sup>-1</sup> at the band center of each of the filtered optical pathways possessed by the OCAMS instruments, as shown in Equation 10.

**Table 3 OCAMS Panchromatic Filter Radiance Responsivities to reflected solar light within the band (DN sec<sup>-1</sup>) / (W m<sup>-2</sup> sr<sup>-1</sup>)**

MapCam	Pan	Pan-30

SamCam	Pan 1	Pan 4	Pan 5	Diopter	
	301088	304742	301583	307223	

**Radiometric Calibration to Spectral Radiance (1024x1024 array size)**

For the color filters, radiometric calibration to spectral radiance converts the signal rate in DN/sec to spectral radiance in W m<sup>-2</sup> μm<sup>-1</sup> sr<sup>-1</sup> at the band center of each of the filtered optical pathways possessed by the OCAMS instruments, as shown in Equation 10.

**Table 4 OCAMS MapCam Color Filter Spectral Radiance Responsivities to reflected solar light within the band (DN sec<sup>-1</sup>) / (W m<sup>-2</sup> μm<sup>-1</sup> sr<sup>-1</sup>)**

MapCam	b	v	w	x
	24644	32443	60085	55314

As with all silicon-based detectors, the responsivity of the OCAMS CCDs are thermally dependent and that dependence is coupled with wavelength. The responsivities listed above for the OCAMS cameras were measured at room temperature, but flight operations will take place at colder temperatures. As such, responsivity has a linear temperature dependence for each filter. When OCAMS images are converted to radiance, the responsivity term is first adjusted for this dependence, listed in Table 5.

**Table 5: Thermal-spectral responsivity dependence**

Camera / Filter	Thermal-spectral responsivity slope ( $^{\circ}\text{C}^{-1}$ )	Reference Temperature ( $^{\circ}\text{C}$ )
MapCam / $b'$	-0.0014	30.2
MapCam / $v$	-0.00075	30.0
MapCam / $w$	0.00053	30.1
MapCam / $x$	0.003	26.6
MapCam / pan	0.00075	28.6
PolyCam / pan	0.00075	27.2
SamCam / pan	0.00075	29.6

$$tsr' = (1 + (T_{ccd} - T_{ref}) * tsr) \quad (11)$$

$$RCC' = RCC * tsr' \quad (12)$$

where  $T_{ccd}$  is the temperature of the CCD at the time of the image,  $T_{ref}$  is the temperature at which the nominal responsivity was measured,  $tsr$  is the slope of the temperature-spectral responsivity dependence,  $RCC$  (see Eq. 10) is the nominal responsivity for that filter at the reference temperature, and  $RCC'$  is the adjusted responsivity.

### **Radiometric Calibration to Reflectance (I/F)**

From the values in Table 3 and 4, combined with the solar irradiance standards displayed in Table 6, the I/F of each observed surface can be produced using the relationship (from eqn. 19 of reference 4):

$$\frac{I}{F} = L * \pi * \frac{D_{sun}^2}{E_{band}} \quad (13)$$

where

$r$  is the range to the Sun (AU); this is derived from the mission profile, usually passed through the image header which uses the tool spatialgen to produce the range

$t$  is the integration time (sec);

$I$  is the intensity (radiance), or spectral radiance, present at the surface of the target at a specific location corresponding to the pixel (either  $\text{W m}^{-2} \text{sr}^{-1}$  or  $\text{W m}^{-2} \text{sr}^{-1} \dots$  depending upon whether one is considered panchromatic data (the former) or colored filter bandpass data (the latter) (I/F is provided within the L2 image);

$F$  is the solar intensity (radiance) within the band illuminating the target at  $0^{\circ}$  phase ( $\text{W m}^{-2} \text{sr}^{-1}$  or  $\text{W m}^{-2} \text{sr}^{-1} \dots$ );

$L$  is the radiance measured by the OCAMS detector within the band at the pixel ( $\text{W m}^{-2} \text{ sr}^{-1}$  or  $\text{W m}^{-2} \text{ sr}^{-1} \dots \text{m}^{-1}$ );

$E_{band}$  is the Sun's irradiance or spectral irradiance within the band at 1 AU (See Tables 6 or 7).

**Table 6 Solar Irradiances  $E_{band}$  ( $\text{W m}^{-2}$ ) used in converting to I/F**

### **Availability of Calibration Files on SPOCFlight**

Internally, calibration files are distributed to the team in a convenient fashion by making them available on SPOCFlight. On this system, one selects Engineering Calibrations Select Instrument Cams, Select Calibration (one of several choices). They are time-tagged with a Start and Stop Date (e.g., 20160301100000 for yyymmddhhmmss) to delimit the time period over which they are intended to apply. *These files are available to PDS users in the OCAMS Bundle Calibration collection. Files used to correct a particular image are listed in that image's label reference list.*
